Fifty otosclerotic samples were examined by the microradiographic technique. The developmental stage of the otosclerotic process was thus attempted to be elucidated. Grouping by Henner et al. (1960) was employed. Out of the samples with normal crystalline structure 30 % represented the fourth stage, 30 % the third, 17 % the second and 23 % the first. As to the samples with an abnormal crystalline structure 30 % belonged to the fourth stage, 40 % to the third, 20 % to the second and 10 % to the first. All samples with amorphous structure belonged to the fourth developmental stage.

The mineral contents were determined from the anterior part of 20 normal staped-

ial footplates. The average calcium content was 30.28 phosphorus 15.96 sodium 0.43 and magnesium 0.34 mg/100 mg bone.

Forty otosclerotic samples were selected for the mineral analysis. In the group with the normal crystalline structure the average calcium content was 25.85 phosphorus 13.87 sodium 0.41 and magnesium 0.26 mg/100 mg bone. In the group with an abnormal crystalline structure, the average calcium content was 24.70 phosphorus 14.27 sodium 0.36 and magnesium 0.23 mg/100 mg bone. In the group with amorphous structure the average contents were as follows for calcium 18.24 phosphorus 10.51 sodium 0.35 and magnesium 0.18 mg/100 mg bone.

The calcium and phosphorus contents in the otosclerotic group with the normal crystalline structure were statistically significantly lower than those of the normal stapedial footplate, and the magnesium content was nearly significantly lower In the group with the abnormal structure as well the calcium and magnesium contents were significantly lower Between the otosclerotic samples with normal and abnormal structures no significant differences were noted for any of the minerals. On the other hand, the calcium and phosphorus contents in the otosclerotic samples with amorphous structure were highly significantly lower than those of the normal stapedial footplate or otosclerotic bone with the normal crystalline structure.

The present investigation reveals that otosclerotic bone with amorphous structure represents the youngest, most active otosclerotic focus, in which bone crystals have not developed yet or in which they are very small. Similarly the mineral contents in an otosclerotic focus of this type are clearly lower than in otosclerotic bone with the normal crystalline structure. On the other hand, abnormal crystalline structures obviously appear even at other otosclerotic stages, and this kind of otosclerotic bone hardly differs from normal otosclerotic bone It is concluded that abnormal crystalline structures are apparently caused by alterations in the organic component of otosclerotic bone.

VII Summary

The aim of the study was to investigate by the Debye Scherrer method the crystalline structures of normal auditory ossicles and otosclerotic bone by comparing them with the crystalline structure of normal human bone. In addition crystal orientation in normal auditory ossicles and otosclerotic bone was investigated by the Laue transmission method. By virtue of the microradiographic examination the present author attempted to find out at what developmental stage of otosclerosis alterations in the crystalline structure appear Finally the mineral contents of the normal stapes and different otosclerotic foci observed by the x ray crystallographic examination were studied. The calcium and magnesium contents were determined by atom absorption spectrophotometry and the phosphorus and sodium contents by neutron activation analysis

The auditory ossicles of 10 deceased with no history of impaired hearing were examined by the Debye-Scherrer method Powder patterns were made of seven different locations of the ossicular chain All diffraction patterns were identical with that of normal human bone As well the diffraction patterns of the posterior meatal wall of controls and otosclerotics were identical with the pattern of normal hydroxyapatite

The auditory ossicles of 10 deceased with no history of impaired hearing were examined by the Laue transmission method. It was noted that the bone crystals were arranged parallelly with the collagen fibrils In the stapedial footplate however great variation was noted in the bone crystal orientation

The otosclerotic material consisted of 250 samples obtained in connection with operations for otosclerosis They were pieces of otosclerotic stapedes or separate otosclerotic foci In the Debye-Scherrer examination, a diffraction pattern of normal hydroxyapatite was obtained in 75 % an abnormal pattern in 7 % and a pattern typical of amorphous structure in 18 % As to the stapedial foot plate alone in 73 % of the 237 samples examined the diffraction pattern was that of normal hydroxyapatite 8 % gave an abnormal pattern and 19 % a pattern showing amorphous structure. The patterns of the different crystalline structures did not correlate in any way with the sex or age of the patients or original location of the sample

Bone crystal orientation was examined in 50 otosclerotic samples In 24 % a more or less preferred orientation was noted where as no preferred orientation was seen in 68 % In the samples with the normal crystalline structure preferred orientation was observed in 25 % whereas in the samples with the abnormal crystalline structure preferred orientation was seen in 20 % and no preferred orientation in 80 %

Fifty otosclerotic samples were examined by the microradiographic technique The developmental stage of the otosclerotic process was thus attempted to be elucidated Grouping by Henner et al (1960) was employed Out of the samples with normal crystalline structure 30 % represented the fourth stage 30 % the third 17 % the second and 23 % the first As to the samples with an abnormal crystalline structure 30 % belonged to the fourth stage 40 to the third 20 to the second and 10 to the first All samples with amorphous structure belonged to the fourth developmental stage

The mineral contents were determined from the anterior part of 20 normal staped

Abstract

This is a method of anaesthesia wich produces a deep, residual analgesia and neurolepsia, in which the activity of the autonomic nervous system is markedly reduced. Non-depressed, completely spontaneous respiration is to be compared with that seen in normal subjects at night during a period of so-called deep sleep ("Protected Sleep") In our opinion, this is a factor of great importance, enabling the preservation of (1) a constant pCO_2, (2) a central and peripheral circulation without any vasoconstrictions, and (3) a constant and low venous pressure, in the operative as well as in the postoperative phase, without any sudden transition.

This state is further characterized by a relative arterial hypotension, a good peripheral and tissue circulation and a mild hypothermia. In this way we can obtain a surgical field with minimal bleeding, no oozing and with good conditions for operating in ENT surgery (especially microsurgery of the ear), neurosurgery ophthalmic surgery and maxillo-facial surgery

The postoperative period is characterized by a calm and gradual awakening. The method is described on a clinical and practical basis. Theoretical considerations are being kept to a minimum and included only in order to clarify particular aspects.

Abstract

This is a method of anaesthesia wich produces a deep, residual analgesia and neurolepsia, in which the activity of the autonomic nervous system is markedly reduced. Non-depressed, completely spontaneous respiration is to be compared with that seen in normal subjects at night during a period of so-called deep sleep ("Protected Sleep"). In our opinion, this is a factor of great importance, enabling the preservation of (1) a constant pCO_2, (2) a central and peripheral circulation without any vasoconstrictions, and (3) a constant and low venous pressure, in the operative as well as in the post operative phase, without any sudden transition.

This state is further characterized by a relative arterial hypotension, a good peripheral and tissue circulation and a mild hypothermia. In this way we can obtain a surgical field with minimal bleeding, no oozing and with good conditions for operating in ENT surgery (especially microsurgery of the ear) neurosurgery ophthalmic surgery and maxillo-facial surgery

The postoperative period is characterized by a calm and gradual awakening. The method is described on a clinical and practical basis. Theoretical considerations are being kept to a minimum and included only in order to clarify particular aspects.

A General Aspects of the Technique

1 Arterial Hypotension

Before deliberately inducing even a moderate degree of arterial hypotension, one should always take care and make sure *that no harm* whatsoever might result (Rollason & Hough, 1960 Rollason, 1965 Slack & Walther 1964 Larsen, 1964 Conley Hincks & Jasaitis, 1965). In our opinion, induced arterial hypotension carries risks in application when one or more of the three following circumstances are present.

(*a*) a relative cellular hypoxia and insufficient tissue perfusion (a theoretically *unavoidable* consequency *of respiratory alkalosis and thus* of controlled hyperventilation (Andrew & Roth, 1968 Rengachery Roth, Andrew & Mark, 1967 Wollman, Craighead, Cohen, Smith, Chase & van der Molen, 1965 Keuskamp, 1965 Wollman, Smith, Stephen, Colton, Gleaton & Craighead, 1968 Tindall, Craddock & Greenfield, 1967)

(*b*) *an insufficient suppression* of neuro-vegetative activity with still possibility of vivid adrenergic baroreceptor and other reflexes with the consequent possibility of important peripheral vasoconstrictor reactions. That is to say too light anaesthesia and insufficient analgesia (Williams & Jones, 1968).

(*c*) a enous pressure not stabilized at a slightly lower value than preoperatively

These are the principal reasons why we abandoned controlled ventilation and light anaesthesia and searched for a spontaneous, non-depressed respiration together with a deeper degree of anaesthesia with sufficient depression of autonomic nervous activity

2. Spontaneous Respiration and Deep Narco-neuroleptanalgesia

The described anaesthetic technique permits a *completely* spontaneous respiration comparable to that of a normal subject at night during a period of so-called, deep-sleep Protected Sleep

The average values for the pCO_2 and the pH illustrate the same phenomenon (Comroe, 1966) (see further in Control Investigations). This can be achieved by means of the combination of drugs we use and which will be discussed *later*

Keeping in mind that CO is the only physiological vasodilatator (Molnar & Seylaz, 1967 Loew Palleske & Herrmann, 1967) it would seem preferable not to wash out the normal CO_2 stores of the body by means of artificial ventilation, when one is not really obliged to do so. On the contrary it would seem desirable, physiologically to maintain a fairly constant pCO_2, even slightly more on the acid side, *close to the limits of normal values but without* metabolic acidosis.

Sufficiently deep anaesthesia and maintenance of an adequate spontaneous respiration will guarantee a central and peripheral circulation, without vasoconstriction. Consequently a nearly normal state in the capillary circulation, in tissue perfusion and in tissue oxygenation is achieved.

At the same time we are able to avoid postoperative *hypoventilation* and *hypoxia* which normally occur after a classic *hyperventilation* technique. This period of hypoventilation with respiratory CO_2 retention occurs in order *to*

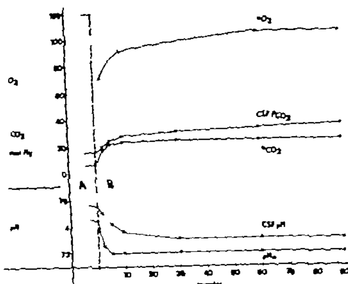

Fig. 2. Arterial and cisternal CFS gas tensions and pH during spontaneous recovery from hyperventilation. Period *A* hyperventilation with air for 60 min. Period *B* mechanical ventilation discontinued, allowing spontaneous return of breathing. Sullivan, S. F et al. (Ibid.), 1967

Nalorphine, muscular rigidity or any other extrapyramidal symptoms. With this drug we are able to obtain the constant, low venous pressure that is our goal. This low venous pressure is a result of the normo-physiologic venous return to the right heart during spontaneous inspiration, together with arterial hypotension and dilated capillary bed. Moreover this drug possesses analgesic properties of its own (Courvoisier & Leau, 1959 Lasagne & De Kornfeld, 1961 Maxwell, Palmer & Ryall, 1961 Paradis, 1962 Montilla, Frederik & Cass, 1965 Bloomfield, Simard-Savoie, Bernier & Tetreault, 1964 Kast & Collins, 1966 Beaver Wallenstein, Houde & Rogers, 1966 Council on Drugs, 1968).

Some of the recently developed active synthetic analgesics have been tried. They have not proved ideal for our purpose when used in large doses, since they produced a marked depression of respiration (Benzer Brunner Lempert & Muhar 1967 Benzer Brunner Lempert, Muhar & Pall, 1968).

Neither was simultaneous administration of a certain dose of Nalorphine a success. In fact, when using these drugs, artificial ventilation is an absolute necessity and for our purpose we do not want this unphysiological respiration.

For this reason we have returned to the use of Pethidine. This synthetic analgesic is fairly well-known (Goodman & Gilman, 1965), it is not too potent and permits simultaneous administration of Nalorphine (Goodman & Gilman, 1965). In a proportion of 10 mg N Allyl-Normorphine to 300 to 400 mg Pethidine adequate spontaneous respiration is maintained (Foldes, Schapira, Tarda, Duncalf & Shiffman, 1965 Foldes & Tarda, 1965). In this way one of the most outstanding side effects of this morphinomimetic drug is suppressed. Consequently it is possible to give a much larger dose of Pethidine and thus achieve a comfortable analgesic and hypnotic action.

In the intramuscular premedication we may also include Promethazine (Courvoisier Ducrot & Julou, 1957 Kinross-Wright, 1967) to reinforce hypnosis and Diazepam (Brandt & Cakes, 1965 Jaquenoud, 1965 Tornetta, 1965 Touchard & Bobin, 1966 Beaulieu, Boyette, Keeri-Saanto & Rheault, 1967) to reinforce the degree of general relaxation. In the doses used, these drugs do not depress spontaneous respiration (Steen, Weitzner Amaha & Martinez, 1966).

In 1969 we also used Diazepam as an intravenous induction agent, instead of thiopentone, so far with excellent results (Dalen, Evans, Banas, Brooks, Paraskos & Dexter

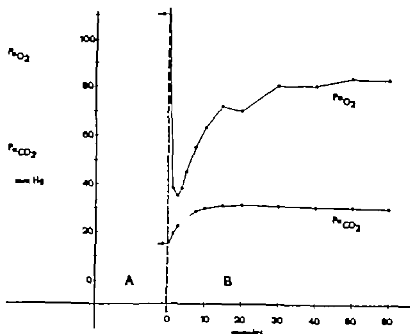

Fig 1 Posthyperventilation blood gas tensions. Period *A* represents steady hyperventilation with air for 60 min. Period *B* mechanical ventilation discontinued, allowing spontaneous return of breathing.
Sullivan, S. F., Patterson R. W & Papper E. M Department of Anesthesiology College of Physicians and Surgeons, Columbia University New York City Posthyperventilation hypoxia. *J Appl Physiol 22* (3) 431 5 1967

restore the depletion of CO_2 stores of the body (Salvatore, Sullivan & Papper 1969 Markello, Cutter & King, 1963 Marshall & Millar 1965) (Figs. 1 and 2) Furthermore, it is also possible to obtain a constant and low venous pressure during the operative, as well as the immediate postoperative periods, without any sudden transition This is mainly due to the normal physiological venous return to the right heart and which flows unchanged and unhindered *during spontaneuos inspiratory thoracic expansion.*

In these circumstances even with a certain degree of arterial hypotension, *the normal gradient of the tissue blood flow will be maintained*

A better surgical field is produced with fewer postoperative complications, whilst the induced state will return only very gradually to the preoperative state

With all this in mind we no longer use artificial ventilation for surgery of the head and neck In fact this kind of surgery by itself does not require curarization or a similar state, but a surgical field with minimal bleeding and free from vascular congestion (Conley Hincks & Jasaitis 1965) Our anaesthetic equipment has been reduced to a minimum whilst the pharmacodynamic part of anaesthesia has increased in importance.

3 Pharmacodynamic Medication

In order to obtain the anaesthetic state of Protected Sleep" we use a pharmacodynamic mixture, based on the association of the following drugs. Pethidine (Meperidine) N Allyl Normorphine, and Levomepromazine (Methotrimeprazine) *(P N.L. mixture) The choice of this* medication was made only after the most careful clinical tests, carried out with other known neuroplegics and analgesics.

In order to achieve the desired degree of neurolepsia we are at present using Levomepromazine, a phenothiazine derivate This drug possesses interesting autonomic nervous depressing effects, orthosympathicolytic and parasympathicolytic *(Julou Ducrot & Fouche,* 1966 Courvoisier Ducrot, Fournel & Julou 1957 Courvoisier Ducrot & Julou, 1957 Kinross-Wright 1967 Laborit, 1959 Du Cailar 1961 Decourt 1959 Dobkin, Levy Ounkasem & Pieloch 1968).

Besides, even very high doses do not interfere with spontaneus respiration. *Nor have* we observed, in combination with Pethidine–

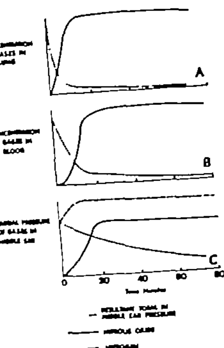

Fig. 3 (*A*) show rapid increase of pulmonary nitrous oxide with concomitant decrease in nitrogen concentration. This is associated (*B*) with similar changes in blood. This results in rapid increase of nitrous oxide partial pressure in the middle ear associated with gradual decrease in the partial pressure of nitrogen, resulting in an increase in middle ear pressure (*C*).

Matz, G. J. Rattenborg, C. G. & Holaday, D. A. Section of Otolaryngology and of Anesthesiology University of Chicago School of Medicine, Chicago. Effects of nitrous oxide on middle ear pressure. *Anesthesiology 28* 948–60, 1967

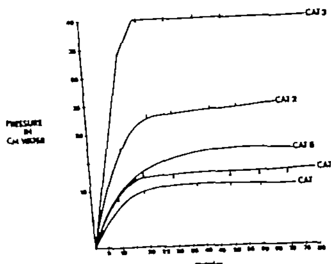

Fig 4 In 5 cats studied, middle ear pressure rose to 12 to 40 cm of water. After 25 min middle ear pressure remained constant.

Matz, G. J. et al. (ibid.), 1967

the absorption of nitrogen will lag behind in the process of equalization (Figs. 3 4).

When using a purely pharmacodynamic parenteral technique of narcosis, spontaneous breathing of normal air at room temperature and at atmospheric pressure continues throughout the operation (Delaruelle & Marquet, 1966 Delaruelle, 1968).

In contrast to classic inhalation anaesthesia there are no changing partition coefficients of gases in the middle ear. Because the classic additives in anaesthesia such as nitrous oxide or Halothane are completely lacking, one should not be afraid of giving an adequate dose of the pharmacodynamic mixture already mentioned. For the same reason we keep to the

1969 Baker 1969 Doult, 1965) In this way the transient cardiovascular and respiratory depression of the barbiturate is avoided.

4 Points of General Interest and Possibilities of Protected Sleep

It is of interest to note that the success of the technique would seem to depend on the *administration of a sufficient dose from the start* adapted of course to age general condition and degree of nervousness of each patient. With this narco-neuroleptanalgesia we can obtain a surgical field with minimal bleeding, minimal oozing and with good conditions for dissecting in fields of E.N T surgery (particularly ear surgery) neurosurgery ophthalmic surgery and maxillo-facial surgery

Our observations have shown. (*a*) a microsurgical field with minimal bleeding and minimal oozing (functional ear surgery microscopic neurosurgery) (*b*) a low cerebro-spinal fluid pressure (*c*) a decreased brain volume (*d*) a low intraocular tension (ophthalmology) (*e*) a very gradual and calm recovery with little or no postoperative cerebral oedema, lesser postoperative hyperthermia, and no postoperative hemorrhage (*f*) in neurosurgery an immediate control of the respiratory centre is possible throughout the operation.

B Practical Application of the Technique

1 Functional Ear Surgery

A too-often disregarded problem in otological surgery is the type of anaesthesia used. Among the many works published on ear surgery those discussing or even mentioning this problem are extremely rare. It is nevertheless certain that anaesthesia in itself plays a role in the outcome of surgery be it simply local anaesthesia, loco-regional anaesthesia with or without premedication, or general anaesthesia with or without controlled respiration. The patient is brought temporarily into an abnormal and artificial physiological state from which the physiological cochlear equilibrium cannot avoid influence. Most often, however these considerations are not borne in mind, generally because of lack of interest on the part of the surgeon.

I believe that in the surgery which interests us here, we need to ensure not only good anaesthesia in which the reactivity of the autonomic nervous system is markedly reduced but also that the cessation of anaesthesia at the end of the operation does not provoke a sudden alteration in the equilibrium obtained during the period of an esthesia, especially that affecting the labyrinthine circulation (Marquet, 1970)

When performing middle ear surgery under inhalation anaesthesia administered by orotracheal intubation, the surgeon often observes a bulging of the tympanic membrane, of the fascia or veingraft or of the homograft. The bulging increases until it is so pronounced that gas escapes from under the edge of the graft. The eardrum or the graft is seen to collapse, but soon the bulging will reappear Quite obviously a positive pressure is generated in the middle ear This phenomenon is caused by nitrous oxide The essential factor is the difference between the partition coefficients of nitrous oxide and nitrogen (Thomson, Terkildsen & Arnfred, 1965 Rasmussen, 1967 Waun, Sweiter & Hamilton 1967 Matz, Rattenborg & Holaday 1967 Foldes, Kapes & Ship, 1965)

The solubility in blood of nitrous oxide is thirty times larger than for nitrogen and thirty times more nitrous oxide than nitrogen can be carried at the same partial pressure As a consequence of this difference the blood arriving at the middle ear can discharge a large quantity of nitrous oxide into the cavity and

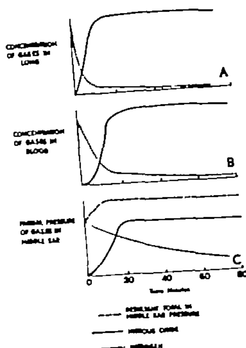

Fig. 3 (*A*) show rapid increase of pulmonary nitrous oxide with a concomitant decrease in nitrogen concentration. This is associated (*B*) with similar changes in blood. This results in rapid increase of nitrous oxide partial pressure in the middle ear associated with gradual decrease in the partial pressure of nitrogen, resulting in an increase in middle ear pressure (*C*).

Matz, G. J. Rattenborg, C. G. & Holaday D. A. Section of Otolaryngology and of Anesthesiology University of Chicago School of Medicine, Chicago. Effects of nitrous oxide on middle ear pressure. *Anesthesiology 28* 948–60, 1967

Fig. 6. Bed ready to receive patient still in the state of "Protected Sleep

Once the patient has been put back to bed in a correct attitude, the postoperative control becomes very simple. It consists only of checking pulse rate, respiration, temperature and blood pressure. Putting the patient back to bed is done with special care and attention because of the prevailing general muscle relaxation, vasoplegia, low venous pressure, relative arterial hypotension and absence of muscle activity (Fig. 6).

Any point of pressure upon the body must be protected. After every period of 2 hours it is recommended that the patient be slightly moved in order to expose other points of the body to the pressure of the bed surface. One should pay special attention to the coccyx, the pericoccygeal region and the skin on the occipital part of the head (Abel, 1964). Elongation of the plexus brachialis or compression of the ulnar nerve must of course be avoided (Jackson & Keats, 1965 Boulton & Cole, 1967) For all this the patient receives a thick and soft pillow underneath the head and shoulders (the head is turned a little sideward with the chin pointing upward). The arms are folded and a small pillow is put under each elbow The hands are put on the thorax or on the abdomen. A large soft cushion is put underneath the lower extremities. The heels hang free. The blankets are laid over the foot of the bed. In order to avoid also that the ankle joint be brought into extension, the sheets are not fixed underneath the foot of the mattress. One also makes sure that folds neither of pyjamas nor of bed sheets exert any pressure on the pericoccygeal region or on the thighs. During the first 24 hours, blocks (height, 15 to 20 cm) are put under the foot of the bed in order to prevent venous stasis in the lower limbs. (This is an interesting help to any postoperative patient.)

Both corneal and plantar reflexes are nearly always present at the end of the operation. After 1 to 2 hours, the swallowing reflex returns. The oral cannula or tube, however is still tolerated at this time. After a period of 4 to 6 hours the patient can be stimulated and be spoken to He goes to sleep each time, however During the entire first day and night he is only allowed to suck ice cubes (dry mouth).

4 *Further course*

Very rarely postoperative analgesics are needed. If so Methampyrone (Novalgin®) is given by i.m. injection. The next day patient drinks and light food is allowed. In fact, the patients should be encouraged to drink quite a lot, this improves diuresis and excretion of the admin-

— The surgeon starts operation with a local infiltration of about 1 ml of 1 or 2% Prilocaine, Lignocaine or Carbocaine with 0 1 mg Epinephrine. Usually this is done at about 8 mm from the tympanic membrane

The purposes of this infiltration with local anaesthetics are (1) additional local anaesthesia, (2) additional prevention of even minimal bleeding, and (3) to perform an easy dissection of the skin from the external auditory canal. If patient reacts upon local infiltration 5 to 10 mg Diazepam is injected slowly (flooding of vein should follow)

(*b*) During the surgical intervention a small dose of the P N L mixture is given according to routine after about 90 min of operation time or in the event of any reaction of the patient. An additional dose of Diazepam (5 to 15 mg) may also be indicated.

Observations

— We observe a decrease of arterial blood pressure (systolic as well as diastolic) with an average systolic value of 80 to 100 mmHg in normotensive patients

— The venous pressure is low as can be observed clinically in the veins of the extremities and at the jugular vein.

— *Respiration is sufficiently deep and calm*, and there is no bronchial hypersecretion.

— Peripheral circulation is adequate as judged from both the extremities and the microscopic operation field.

— Upon reposition or homograft of the tympanic membrane, the latter does not balloon

Remarks.

(*a*) Children and young adults should receive higher doses of the P N L. mixture than might be expected The doses required depend more on the metabolism of the organism than on the body weight. However multi-fractionated administration of the drugs is in any case the method of choice

(*b*) After the large induction dose of the narco-neuroleptic mixture the autonomic nervous blockade of the sympathic as well as of the vagal system is illustrated, in most patients, by the tendency of the heart rhythm towards tachycardia. After a variable period of time, the physiological vagal preponderance will gradually exert its influence again and slow down the heart to a frequency of 70 to 100 per minute

(*c*) Light hypothermia is a usual consequence of this kind of anaesthesia (±35 to 35 5 C).

(*d*) Spots of intense intracutaneous vasoplegia sometimes appear following the intravenous injection of the narco-neuroleptic mixture. They disappear spontaneously after 20 to 45 min

(*e*) In case of insufficient bloodlessness at the site of microsurgery i v injection of an additional dose of Levomepromazine (25 to 50 mg) and of 0 6 to 0 9 mg. of Hydergin (Goodman & Gilman 1965) in order to reinforce the alpha adrenergic blockade If this is still insufficient, give once more the mixture of Pethidine 100 to 200 mg, Nalorphine 2.5 to 5 mg, Levomepromazine 25 to 50 mg and Diazepam 5 to 10 mg in order to deepen the anaesthesia. In this manner peripheral autonomic nervous reactions which affect the vascular tone may be prevented more effectively If this procedure is also not helpful in preventing bleeding at the operation site, a slow i v injection of one or two vials of Epsilon Amino-Caproic Acid (Capramol® vial containing 2.5 g) (Berger & Pinson, 1964) is recommended. This is on the basis of the hypothesis that in some patients local fibrinolysis may occur at the site of protracted microsurgery because of liberation of tissue kinases.

3 *Immediate postoperative measures*

During this period not the least anaesthesiologic manipulation is required The patient is put to bed again, while still in "Protected Sleep" At this time it is sometimes useful to inject a dose of 5 to 10 mg of *N* Allyl Normorphine intravenously In patients with a cardiovascular or pulmonary handicap this can be supplemented by an intravenous or intramuscular preparation of a Theophylline derivate.

Fig. 6. Bed ready to receive a patient still in the state of Protected Sleep.

Once the patient has been put back to bed in a correct attitude, the postoperative control becomes very simple. It consists only of checking pulse rate, respiration, temperature and blood pressure. Putting the patient back to bed is done with special care and attention because of the prevailing general muscle relaxation, vasoplegia, low venous pressure, relative arterial hypotension and absence of muscle activity (Fig. 6).

(d) Spots of intense intracutaneous vasoplegia sometimes appear following the intravenous injection of the narco-neuroleptic mixture. They disappear spontaneously after 20 to 45 min.

(e) In case of insufficient bloodlessness at the site of microsurgery i v injection of an additional dose of Levomepromazine (25 to 50 mg) and of 0 6 to 0 9 mg. of Hydergin (Goodman & Gilman, 1965) in order to reinforce the alpha adrenergic blockade. If this is still insufficient, give once more the mixture of Pethidine 100 to 200 mg, Nalorphine 2.5 to 5 mg, Levomepromazine 25 to 50 mg and Diazepam 5 to 10 mg in order to deepen the anaesthesia. In this manner peripheral autonomic nervous reactions which affect the vascular tone may be prevented more effectively If this procedure is also not helpful in preventing bleeding at the operation site, a slow i v injection of one or two vials of Epsilon Amino-Caproic Acid (Capramol® vial containing 2.5 g) (Berger & Pinson, 1964) is recommended. This is on the basis of the hypothesis that in some patients local fibrinolysis may occur at the site of protracted microsurgery because of liberation of tissue kinases.

3 *Immediate postoperative measures*

During this period not the least anaesthesiologic manipulation is required. The patient is put to bed again, while still in Protected Sleep" At this time it is sometimes useful to inject a dose of 5 to 10 mg of N Allyl Normorphine intravenously In patients with a cardiovascular or pulmonary handicap this can be supplemented by an intravenous or intramuscular preparation of a Theophylline derivate.

Anaesthetic management

Intramuscular premedication. Pethidine, Levomepromazine and Diazepam. Dose according to clinical state and age of each patient. For example normal adult. Prethidine 100 mg, Levomepromazine 25–50 mg, Diazepam 10 mg.

Induction of anaesthesia: a normal initial C.V dose of Thiopentone 5% (300 to 600 mg for an adult) or an induction dose of Diazepam (20 to 40 mg for an adult) is followed by a more or less large dose of the Pethidine Nalorphine-Levomepromazine mixture according to clinical state and age (from 1/8 to the whole of the mixture) Relative proportions. Pethidine 300 to 400 mg Nalorphine: 7.5 to 10 mg Levomepromazine 75 to 100 mg.

A single dose of suxamethonium 25 to 50 mg to facilitate tracheal intubation is added. The vein should be flooded after the administration of the P.N.L. mixture (see further in Complications)

For maintenance nitrous oxide, oxygen, small amounts of Halothane and additional doses of the mentioned mixture are given. Uni-directional gas flow with the Magill attachment and an expiratory Ruben valve or a similar low resistance valve is provided. Fresh gas flow of 5 to 7 l min, which is largely sufficient to prevent rebreathing (Norman, Adams & Sykes, 1968 Mapleson, 1954). If the neurosurgeon wishes to do so, he may use without fear a local anaesthetic on the skull, even with adrenalin. The induced autonomic nervous blockade is sufficient to reduce reflex sympatho-adrenal activity

At the slightest reaction of the patient (bucking on the endotracheal tube or a slight movement) a certain amount of the P.N.L mixture will be administered without hesitation.

The same applies to a rise in the arterial pressure or an acceleration of the respiration. The quantity of halothane vaporized per hour is minimal (4 to 8 ml) and will depend on essentially two factors. the arterial pressure (kept between 70 and 100 mm of mercury systolic) and no or minimal depression of the spontaneous respiration. If Halothane is administered in higher concentrations the opposite of the desired could be the result (MacDowall, Barker & Jennett, 1966 Jennett et al. 1967 Jennett, Barker Fitch & MacDowall, 1969)

When the arterial systolic pressure reaches 70 mmHg, or if respiration is even but slightly depressed, Halothane administration will be momentarily interrupted.

At the termination of surgery the extubation and the introduction of an oral cannula should be performed as gently as possible without coughing or other tracheal or laryngeal reactions (rise in venous pressure and rise in C.S.F pressure) (Freund, 1968)

We do not hesitate to administer just prior to this manipulation 4 to 5 ml of Thiopentone 5% 5 to 10 mg Diazepam, or even a certain amount of the P.N L. mixture. The endotracheal tube could also be left in situ when desired. In our opinion *the method of the early awakening of these patients on the operation table is to be completely avoided.* The complete recovery of normal reflexes and of normal consciousness should be postponed for several hours and happen as gently and gradually as possible. Because of this prolonged state of Protected Sleep (Figs. 7 8) pressure points should be protected (see further in postoperative management in ear-surgery).

During the surgical procedure, as well as in the postoperative period intravenous fluid therapy and blood transfusion (rarely necessary) should be restricted to a minimum. This is in order to avoid venous pressure rise, C.S F pressure rise, cerebral oedema and postoperative hemorrhage. The brain is most sensitive to water intoxication (Rosomoff, 1968).

During the first hours after the operation analgesics are rarely needed. Later Methampyrone (Novalgin®), in i.m. injection, is the drug we use. As well as an analgesic or as an antipyretic whenever the temperature reaches 38 C.

During 3 to 4 days Phenobarbital (100 to

istered drugs Normal food is given from the second postoperative day

Vertigo is rarely observed after this type of anaesthesia. Obviously the kind of surgical intervention plays a role too. Nausea or vomiting occur very rarely if so Metoclopramide (Primperan®) (Tornetta, 1969 Brassier 1966) is the drug we use. On the third postoperative day the patient can resume his normal activities Postoperative microscopic ear-dressing is done but in case of transplant or homograft of membrana tympani, dressing is only made on the fifth day

The patient can feel a certain buttock stiffness. It disappears with normal muscle activity It is caused mainly by the intramuscular injections.

The patient is discharged from the hospital between the fifth and the tenth postoperative day depending upon the type of operation.

2. Neurosurgery

In the great majority of neurosurgical departments all over the world, pulmonary hyperventilation for neurosurgery remains the technique of choice (Allen & Morris, 1962 Schettini et al 1967 Rheault & Lepage 1967 Gilbert, Brindle & Galindo 1968 Douglas et al 1969 Krumperman, 1969)

This technique is considered to improve operating conditions, to reduce the amount of anaesthetic drugs required for adequate relaxation, to reduce the volume of the brain and the intracranial pressure and to bring about a rapid recovery of consciousness (Pierce, 1964 Gordon 1968) Under usual clinical conditions, however an increase in ventilation decreases arterial pCO_2 and hence cerebral blood flow is lowered This diminished blood flow could completely negate or even reverse the desirable effects produced by increased pulmonary ventilation Most outstanding studies challenge the assumption that hyperventilation because of cerebral vasoconstriction results in reduction of intracranial pressure and brain volume. It has been found that during hyperventilation a decrease in intracranial blood volume was accompanied by a compensatory increase in cerebrospinal fluid volume (Rosomoff, 1963) Some interesting studies have also shown that cardiac output and oxygen uptake are reduced in patients on controlled respiration (Malcolm-Smith Grenvik & Westerholm 1968)

Another point of some interest is the hyperoxygenation which accompanies controlled ventilation. Some investigations have shown that hyperoxygenation by itself produces peripheral vasoconstriction and decreases circulation. Autonomic nervous rather than local metabolic effects are believed to cause these changes (Bergofsky & Bertun, 1966 Bauer & Gravenstein, 1966).

Since much interest surrounds the role of brain pH in the regulation of cerebral blood flow experiments on this object have been performed. They demonstrated that during prolonged hyperventilation a metabolic acidosis develops in the cerebrospinal fluid, due to the accumulation of lactic acid (MacDowall & Harper 1968)

Moreover at a certain moment artificial ventilation must be stopped and after this a quite often stormy recovery period with the absolute necessity of intensive reanimatory care begins. A rebound" cerebral blood flow elevated above normal in the post hyperventilation period due to the cerebrospinal fluid acidosis is most likely to occur (MacDowall & Tarper 1968) Pulmonary and haemodynamic disturbances, postoperative hypoxemia, cerebral oedema, hyperthermia and focal hemorrhage are in fact not uncommon

We wonder whether this is not due in the main to improper operative anaesthetic management, where everything happens in subordination to and in consequence of the predominant concept the lighter the anaesthesia, the quicker the recovery the safer will be the technique

It might seem presumptuous to say so, but we are really convinced that the technique of Protected Sleep has something to offer (Delaruelle, 1968 1969 Delaruelle & Granieri, 1968, 1969)

Anaesthetic management

Intramuscular premedication. Pethidine, Levomepromazine and Diazepam. Dose according to clinical state and age of each patient. For example normal adult. Prethidine 100 mg, Levomepromazine 25–50 mg, Diazepam 10 mg.

Induction of anaesthesia: a normal initial C.V dose of Thiopentone 5% (300 to 600 mg for an adult) or an induction dose of Diazepam (20 to 40 mg for an adult) is followed by a more or less large dose of the Pethidine Nalorphine Levomepromazine mixture, according to clinical state and age (from 1/8 to the whole of the mixture) Relative proportions Pethidine· 300 to 400 mg· Nalorphine. 7.5 to 10 mg· Levomepromazine: 75 to 100 mg.

A single dose of suxamethonium 25 to 50 mg to facilitate tracheal intubation is added. The vein should be flooded after the administration of the P.N L. mixture (see further in Complications)

For maintenance. nitrous oxide, oxygen, small amounts of Halothane and additional doses of the mentioned mixture are given. Uni-directional gas flow with the Magill attachment and an expiratory Ruben valve or a similar low resistance valve is provided. Fresh gas flow of 5 to 7 l/min, which is largely sufficient to prevent rebreathing (Norman, Adams & Sykes, 1968 Mapleson, 1954). If the neurosurgeon wishes to do so, he may use without fear a local anaesthetic on the skull, even with adrenalin The induced autonomic nervous blockade is sufficient to reduce reflex sympatho-adrenal activity

At the slightest reaction of the patient (bucking on the endotracheal tube or a slight movement) a certain amount of the P.N.L mixture will be administered without hesitation.

The same applies to a rise in the arterial pressure or an acceleration of the respiration. The quantity of halothane vaporized per hour is minimal (4 to 8 ml) and will depend on essentially two factors. the arterial pressure (kept between 70 and 100 mm of mercury systolic) and no or minimal depression of the spontaneous respiration. If Halothane is administered in higher concentrations the opposite of the desired could be the result (MacDowall, Barker & Jennett, 1966 Jennett et al., 1967 Jennett, Barker Fitch & MacDowall, 1969).

When the arterial systolic pressure reaches 70 mmHg, or if respiration is even but slightly depressed, Halothane administration will be momentarily interrupted.

At the termination of surgery the extubation and the introduction of an oral cannula should be performed as gently as possible, without coughing or other tracheal or laryngeal reactions (*rise in venous pressure and rise in C.S.F* pressure) (Freund, 1968)

We do not hesitate to administer just prior to this manipulation 4 to 5 ml of Thiopentone 5% 5 to 10 mg Diazepam, or even a certain *amount of the P.N.L. mixture.* The endotracheal tube could also be left in situ when desired. In our opinion *the method of the early awakening of these patients on the operation table is to be completely avoided* The complete recovery *of normal reflexes and of normal* consciousness should be postponed for several hours and happen as gently and gradually as possible. Because of this prolonged state of Protected Sleep" (Figs. 7 8) pressure *points* should be protected (see further in postoperative management in ear-surgery).

During the surgical procedure, as well as in the postoperative period intravenous fluid therapy and blood transfusion (*rarely necessary*) should be restricted to a minimum. This is in order to avoid venous pressure rise, C.S.F pressure rise, cerebral oedema and postoperative hemorrhage. The brain is most sensitive to water intoxication (*Rosomoff, 1968*).

During the first hours after the operation analgesics are rarely needed. Later Methampyrone (Novalgin®), in i.m. injection, is the drug we use. As well as an analgesic or as an antipyretic whenever the temperature reaches 38°C.

During 3 to 4 days Phenobarbital (100 to

istered drugs. Normal food is given from the second postoperative day

Vertigo is rarely observed after this type of anaesthesia Obviously the kind of surgical intervention plays a role too Nausea or vomiting occur very rarely if so Metoclopramide (Primperan®) (Tornetta, 1969 Brassier 1966) is the drug we use. On the third postoperative day the patient can resume his normal activities Postoperative microscopic ear-dressing is done, but in case of transplant or homograft of membrana tympani, dressing is only made on the fifth day

The patient can feel a certain buttock stiffness. It disappears with normal muscle activity It is caused mainly by the intramuscular injections.

The patient is discharged from the hospital between the fifth and the tenth postoperative day depending upon the type of operation.

2. Neurosurgery

In the great majority of neurosurgical departments all over the world, pulmonary hyperventilation for neurosurgery remains the technique of choice (Allen & Morris, 1962 Schettini et al. 1967 Rheault & Lepage, 1967 Gilbert, Brindle & Galindo 1968 Douglas et al 1969 Krumperman 1969)

This technique is considered to improve operating conditions, to reduce the amount of anaesthetic drugs required for adequate relaxation, to reduce the volume of the brain and the intracranial pressure and to bring about a rapid recovery of consciousness (Pierce, 1964 Gordon, 1968) Under usual clinical conditions, however an increase in ventilation decreases arterial pCO_2 and hence cerebral blood flow is lowered This diminished blood flow could completely negate or even reverse the desirable effects produced by increased pulmonary ventilation Most outstanding studies challenge the assumption that hyperventilation because of cerebral vasoconstriction results in reduction of intracranial pressure and brain volume It has been found that during hyperventilation a decrease in intracranial blood volume was accompanied by a compensatory increase in cerebrospinal fluid volume (Rosomoff 1963). Some interesting studies have also shown that cardiac output and oxygen uptake are reduced in patients on controlled respiration (Malcolm Smith, Grenvik & Westerholm, 1968)

Another point of some interest is the hyperoxygenation which accompanies controlled ventilation. Some investigations have shown that hyperoxygenation by itself produces peripheral vasoconstriction and decreases circulation. Autonomic nervous rather than local metabolic effects are believed to cause these changes (Bergofsky & Bertun, 1966 Bauer & Gravenstein 1966)

Since much interest surrounds the role of brain pH in the regulation of cerebral blood flow experiments on this object have been performed. They demonstrated that during prolonged hyperventilation a metabolic acidosis develops in the cerebrospinal fluid, due to the accumulation of lactic acid (MacDowall & Harper 1968)

Moreover at a certain moment artificial ventilation must be stopped and after this a quite often stormy recovery period with the absolute necessity of intensive reanimatory care begins. A rebound" cerebral blood flow elevated above normal in the post hyperventilation period due to the cerebrospinal fluid acidosis is most likely to occur (MacDowall & Tarper 1968) Pulmonary and haemodynamic disturbances, postoperative hypoxemia, cerebral oedema, hyperthermia and focal hemorrhage are in fact not uncommon

We wond r whether this is not due in the main to improper operative anaesthetic management, where everything happens in subordination to and in consequence of the predominant concept the lighter the anaesthesia, the quicker the recovery the safer will be the technique"

It might seem presumptuous to say so, but we are really convinced that the technique of Protected Sleep has something to offer (Delaruelle 1968 1969 Delaruelle & Granieri, 1968 1969)

Camplin, 1968 Terry Daw & Michenfelder 1962 Uihlein, Terry Payne & Kirklin, 1962 Karlsberg & Adams, 1962 Michenfelder Terry Daw MacCarty & Uihlein, 1963 Rollason & Latham, 1963). For this purpose we use Trimethaphan (Rollason & Hough, 1960 Tough, 1950· Forgacs & Saabe, 1967 Robertson, 1959) at a concentration of 5 mg/ml. A test dose of 5 mg is injected intravenously and will be completed by intermittent, repeated doses af 5 to 15 mg with each injection. We prefer this to a continuous drip infusion. During this period we will check even more carefully the peripheral circulation (fingernails, toes), the pulse, the spontaneous respiration (depth and frequency) and of course the arterial tension. Venous pressure, E.C.G and E.E.G recording are of course very interesting but the pity is that in our country they are not always available At the same time 50% N_2O with 50% O_2 will be inhaled, without Halothane.

3 Ophthalmic Surgery

Intraocular pressure is influenced by the same factors as those controlling the volume of the intracranial contents and ophthalmic surgery imposes demands similar to those of neurological surgery (Adams, 1966) In ophthalmic surgery one is frequently confronted on the one hand with older patients, mostly in a poor general condition, or on the other hand with very young patients Neverth.less, the same basic technique can be applied, but the dose of the pharmacodynamic P N L. mixture should be adapted accordingly We can illustrate this with the following examples. In telegraphese·

Cataract or glaucoma surgery Patient 70 to 80 years Poor cardio-vascular and pulmonary conditions Premedication. Pethidine 25 to 50 mg. Levomepromazine 12.5 to 18 75 mg, Diazepam 5 to 5 mg. i.m. Together with it a suppository of a theophylline derivate (250 to 300 mg)

The P N L. mixture produces a pronounced miosis. Instillation of a Epinephrine–Cocaine solution is therefore obligatory in cataract surgery in order to obtain the desired mydriasis. This should be done 1 hour before the operation. Another alternative is a retrobulbar injection of a 4% Procaine solution just after the induction of the general anaesthesia. Anaesthesia. Thiopentone 5% (very slowly)· 300 to 400 mg, (or Diazepam. 10 to 15 mg) Pethidine. 30 to 50 mg; Levomepromazine: 12.5 to 18 75 mg· Nalorphine· 0.5 to 1,5 mg· Succinylcholine: 25 mg (Taylor Mulcahy & Nightingale, 1968). Dilution of the P.N.L. mixture and flooding of the vein with ± 20 ml of normal saline or glucose 5% solution (see further in Complications) Tracheal intubation nitrous oxide, oxygen, halothane. Spontaneous respiration. Ruben valve or similar alternative If necessary during surgery· additional doses of Thiopenton 5% each time 50 to 100 mg or Diazepam 5 to 10 mg, and when necessary a second small dose of the P.N.L. mixture. Gentle extubation, oral cannula.

Installation in bed with protection of pressure points by means of a soft cushion under the shoulders and occiput, a soft cushion under each elbow and a soft cushion under the calves, leaving the heels free. Gentle shifting of the patient every 2 hours in order to prevent any compression or decubitus-effects. Continue as long as the patient stays somnolent.

For ophthalmic surgery in the very young (most often strabismus surgery) we should, however prefer Promethazine before Levomepromazine under the age of 5 years (Eckenhoff, Helrich & Ralp, 1957) It is sufficiently hypnotic and protective but less hypotensive and it is to be preferred because of the lack of maturity and the greater lability of their autonomic nervous system. For this same reason did we not dare to use Diazepam in the very young. With this type of anaesthesia the well known oculo-cardiac reflex which may lead to circulatory crises (Kasper 1967) is no longer to be feared.

For example (again in telegraphese)·
Normal child, 3 years, strabismus surgery Pre

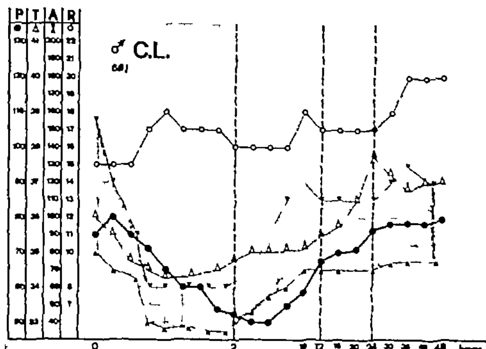

Fig 7 Representation of pulse (*P*), rectal temperature (*T*), systolic and diastolic arterial pressure (*A*) and respiratory rate (*R*) in a male patient, C. L., with a severe chronic bronchitis, operated for a right frontal tumour Duration of surgery 2 hours, 40 min. Parameters after induction of anaesthesia, after h, 12 h, 24 h, and 18 h.

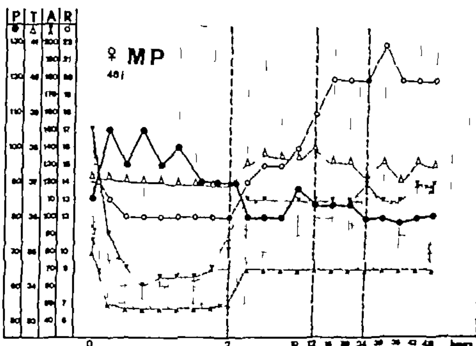

Fig 8 Representation of pulse (*P*), rectal temperature (*T*), systolic and diastolic arterial pressure (*A*) and respiratory rate (*R*) in a female patient, M P in coma for 3 days, operated for a right central cyst. Duration of surgery 3 hours, 15 min Parameters after induction of anaesthesia, after 2 h, 12 h, 24 h, and 48 h.

200 mg i m) is most often given in order to diminish further the effects of the central irritability due to the neurosurgical manipulations or neurological lesions

Intra cranial arterio-venous malformation

The same technique is employed in surgery for intracranial arterio-venous malformations. However during the more delicate phase of this vascular cerebral surgery a reinforced arterial hypotension, down to ±50 mmHg systolic, will *be realized. Thanks to the induced conditions* of sufficient gradient in the tissue blood flow and of moderate hypothermia this short reinforced hypotensive period will be quite well tolerated

It is certainly more controllable and less hard to realize than other techniques such as profound hypothermia, local circulatory arrest extracorporeal circulation or selective brain cooling (Rosomoff 1968 Gott, 1966 Deligne & David, 1966 Hoffmann & Merckx, 1966

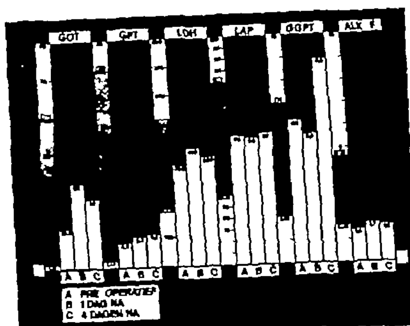

Fig. 9 Average levels of G O T G P T L D.H., L.A.P G.G T P and Alk.Phos the day before, the first day after, and 4 days after anaesthesia in series of patients for microsurgery in the ear

most) but all of them remain within the normal limits of the technique used (Figs. 9 10)

(c) *Electrocardiographic recordings* have *sometimes shown alterations of the ST-segment, the T wave as well as axis-deviations.* These transitory alterations were also seen in younger patients. Indeed, such patients receive relatively higher doses. Consequently their basal metabolism is being altered more *intensively* The E.C.G alterations observed may be the consequence of a generally decreased cell metabolism or cell membrane alterations, expressed at the level of the heart muscle. They may also be the expression of a central neuro-humoral mechanism (Granieri & van Bogaert, 1968 Tsunoda 1964) or of an interference with myocardial biochemistry or contractility (e.g. potassium *extra-intracellular imbalance*) (*List*, 1968 *Laborit*, 1959).

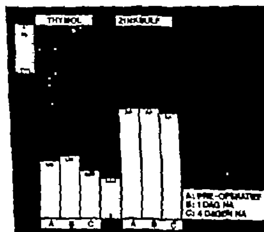

Fig 10 A erage levels of Thymol and Zinc Sulf., the day before, the first day after and 4 days after anaesthesia in series of patients for microsurgery in the ear

Similar E.C.G alterations were found with different phenothiazines (Leak & Carroll, 1967 Goodman & Gilman, 1965). A real myocardial ischemia or infarction is not likely to produce the E.C.G alteration observed after the use of the P.N.L. mixture. The clinical state of the patients, the absence of S G.O T elevation and the *transitory nature of the E.C.G. findings* support this view (*Kelley Cambell & Brandt*, 1967)

Several cardiac patients, either with congenital malformations of the heart or with a history of cardiac infarction have been anaesthetized and have been operated on successfully The same can be said of several patients with other *forms of circulatory insufficiency* Because of

medication Pethidine 25 mg, Promethazine 25 to 35 mg Atropine Sulf 0 3 to 0 5 mg. Anaesthesia. Induction by means of an anaesthetic mask with nitrous oxide oxygen and Halothane Intravenous administration of 100 to 150 mg of Thiopentone 5% followed by Pethidine ± 25 mg, Promethazine 25 to 40 mg and ± 20 mg of Succinylcholine. Gentle intubation with an appropiate size of tube. Nitrous oxide oxygen Halothane. Spontaneous respiration Gentle extubation of the still sleeping child and installation in bed with an oral cannula in situ

Remarks.

For operative procedures such as enucleation without or with an implant or for dacryo-cystorhinostomy the same reinforced arterial hypotension with Trimetaphan as described for arteriovenous malformations in neuro-surgery will be realized

Quite frequently glaucoma patients received potent diuretic agents before coming to the hospital. These result in a potassium depletion. Anaesthesia and neurolepsia also provoke a certain degree of hypokalemia (Laborit, 1959 1959 Du Callar 1961) Thus, potassium should be administered to these patients before and after operative treatment.

4 Maxillo-facial and E.N T Surgery

The same technique as for neurosurgery and ophthalmic surgery is suited to maxillofacial and E.N T surgery The only exception being functional ear surgery (Delaruelle & Marquet, 1966)

C Control Investigations

All the control investigations were performed in the ear surgery series. Indeed only here is the parenteral route alone used for anaesthesia. There is no possible interference from other anaesthesic agents, gases vapours or even of oxygen administration

(a) During the first hour following surgery the most critical period" an Astrup capillary blood control has been made in a series of patients The results show a very mild degree of purely respiratory acidosis The average values are for the pCO_2 46 mmHg and for the pH 7 38 The two extreme values obtained are respectively 40 mmHg and 51 mmHg (this in a chronic bronchitis, with emphysema) and 7 46 and 7 32 for the pH

These results are similar to those found in non anaesthetized subjects, at night during a period of so-called deep sleep (Comroe, 1966) Metabolic acidosis is not present. The average values are for the Base Excess − 1 mEq/l, and for the Standard Bicarbonate, 23 8 mEq/l The two extreme values obtained are, respectively − 3 mEq/l and + 5 mEq/l for the Base Excess, and 21 mEq/l and 28 mEq/l for the Standard Bicarbonate.

Since metabolic acidosis accompanies cellular hypoxia we might conclude that the cellular perfusion and oxygenation stayed within normal limits (Schmier 1969)

(b) Liver function tests were performed in the laboratory of the Bunge Institute (Mr Swinnen, biologist) Levels of some cell and secretion enzymes were assayed before and after anaesthesia for ear surgery in addition to serum bilirubin and two flocculation tests. G O T (Reitman & Fränkel), LDH (Cabaud & Wroblewski) G G T P (Swinnen), L A P (Weber) Alkaline phosphatase (Bodanski) Thymol (MacLagan with buffer according to Reinholds) Zinc sulfate (Kunkel) and Bilirubin (Weber and Schalm)

The results show the expected influence on the secretory function of the liver but no hepatoxic influence The activities of serum enzymes increase in a variable manner (GGTP

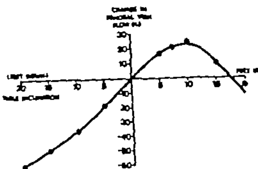

Fig 11 Experiments in greyhounds have been conducted to assess the effect on venous return of varying degrees of operating-table tilt. The mechano-haemodynamic response of the enous system of the greyhound hind limb is almost identical with that in man. Changes in the mean venous-flow rates were measured by electromagnetic *flow* probes placed around the exposed femoral eins. The results indicate that for optimal promotion of venous return the bed should be inclined at 10 to the horizontal.

Roberts, V C., Department of Biomedical Engineering King College Hospital Medical School, London *The Lancet 7653* 948, May 1970.

introduce most often a catheter in a large vein and flush after each injection.

Twenty-six times we encountered a clinical thrombophlebitis in the legs and eleven times a mild but clinically unmistakable lung embolism All these patients were discharged in good health. Nine of these lung embolisms occurred in female patients. We do not know if these patients were taking contraceptive pills. Today when we encounter a patient with manifest varicosities or with a history of venous insufficiency in the lower limbs, a prophylactic treatment with a Hydergin prepartion (PH 203 Sandoz) is administered by i.m injection, for 3 to 5 days postoperatively The use of a 10 head down position during the first 24 hours might also prevent to some extent these vascular complications (Fig. 11).

Seven times we encountered a transient ulnar nerve palsy and once a branchial plexus injury The first case of transient ulnar nerve palsy was a young man who afterwards underwent a careful neurological examination and a electromyographic study A very superficial ulnar sulcus at the elbow could be demonstrated. During surgery the patient's arm had been lying on an ordinary lateral armboard. With physiotherapy and vitamin B therapy the nerve recovered in 6 months.

A more embarrassing complication was that of a 65-year-old male patient, whose arm had also been lying on a lateral armboard and who developed an ulnar nerve and a medial nerve injury after surgery Postoperative examinations showed an advanced degree of cervical ankylosing spondylitis.

Since these occurrences, we no longer use an arm rest but, whenever possible, cross the arms on the abdomen and protect shoulders and the elbows with soft cushions.

Postoperative mental disturbance (Blundell, 1967) that could be attributed to a senile or presenile dementia occurred in 19 patients. They were all over the age of 60 Two cases were operations for trigeminal neuralgia and the rest of them were all intraocular surgeries. Most bad risk and hyperanxious patients belong to the same series. Today whenever we can find in the history of these older patients the slightest hint of manifest malnutrition or of somewhat presenile or senile psychotic behaviour we hydrate the patient intravenously and at the same time administer a certain amount of potassium. An intramuscular purified liver extract (Neo-Hepatex® Evans) is also given for 3 to 4 days. This may seem unimportant, but we do this with the idea of fortifying these older patients. It goes without saying that the dose of the P.N.L. mixture should be most carefully adapted in these cases.

the prevailing complete peripheral vasodilatation and the low venous pressure the relative arterial hypotension is less dangerous in this method. The *normal blood flow* gradient remains here. The myocardial work load function also seems diminished but decreased peripheral vascular resistance permits the heart to maintain a greater forward output than would be possible if aortic pressure remained high (Siegel, 1969)

This does not occur in methods of artificial ventilation as used in light anaesthesia, where a certain degree of vasoconstriction and a higher venous presure are always found. This way both tissue perfusion and oxygenation are impaired in advance. Such a condition is, as already stated, potentially dangerous.

In Protected Sleep" *haemodynamic* pressure changes always occur very gradually There are never any sudden transitions. This is also true at the end of the surgical intervention.

D Complications

Having applied the technique for 9 years we venture to say that this technique is safe. We also venture to assume that no death occurred as a direct consequence of the anaesthetic technique in itself.

Out of a total of 5 628 8 patients died on the operative day and 46 others died during hospitalisation. 37 of these 54 in the neuro-surgical series due to preexisting irreversible neurological damage. One death (in 1963) was that of a glaucoma *female patient of 72 years who died 6 days* postoperatively Preoperatively she had received for several days, large doses of a potent diuretic (Diamox®) After surgery she had shown mental disturbance and a starvation syndrome. We think that the anaesthesia and the neurolepsia precipitated the already existing potassium imbalance and caused irreversible damage One other death was that of a pale, fatty 3-year-old boy operated on for strabismus. The *following morning the boy presented a shock" syndrome and could not be reanimated.* We are unable to explain the exact reason for this lethal complication Autopsy seemed to reveal an impaired desintoxication function Pethidine, Nalorphine and Promethazine could be extracted from liver and kidney tissue. The boy had also *received* Halothane and during the post operative night a suppository *of* Aspirin–Phenacetin–Codein. The *other deaths* were due to various causes but had one *factor in common* All of them were bad risk" patients

Decubitus lesions were encountered in 76 patients. Fortunately only three of them were severe. The great majority of the cases occurred during the first years of application of the technique. At that time we had not yet fully realized that decubitus and local compression are always possible whenever a patient remains *immobile for several hours. Especially after* hypotensive anaesthesia and when lying on the hard, thick rubber pads which our hospitals use to protect their mattresses. Now we pay special attention to the protection of pressure points (see chapter on immediate post-operative measures) and recommend the nursing staff to move the patient slightly every 2 hours.

The lesions encountered were mostly *local*ised in the pericoccygeal area. *Treatment consisted of an intravenous infusion of* 500 ml Rheomacrodex® with 3 to 4 ml heparin. A four times daily application of Butazolidine® ointment completes this therapy

Local induration of a vein after i.v injection of the mixture of drugs was seen in 208 patients.

Dilution of the *Pethidine and the rest of the mixture in a sufficient amount of normal saline or glucose* 5% makes this minor but undesirable side effect much less frequent. Today we

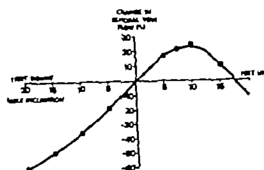

Fig. 11. Experiments in greyhounds have been conducted to assess the effect on venous return of varying degrees of operating-table tilt. The mechano-haemodynamic response of the venous system of the greyhound hind limb is almost identical with that in man. *Changes in the mean cross-flow rates were* measured by electromagnetic flow probes placed around the exposed femoral veins. The results indicate that for optimal promotion of venous return the bed should be inclined at 10° to the horizontal.

Out of a total of 5 628 8 patients died on the operative day and 46 others died during hospitalisation. 37 of these 54 in the neuro-surgical series due to preexisting irreversible neurological damage One death (in 1963) was that of a glaucoma female patient of 72 years who died 6 days postoperatively Preoperatively she had received for several days, large doses of a potent diuretic (Diamox®) After surgery she had shown mental disturbance and a starvation syndrome. We think that the anaesthesia and the neurolepsia precipitated the already existing potassium imbalance and caused irreversible damage One other death was that of a pale, fatty 3-year-old boy operated on for strabismus The following morning the boy presented a shock" syndrome and could not be reanimated. We are unable to explain the exact reason for this lethal complication Autopsy seemed to reveal an impaired desintoxication function Pethidine, Nalorphine and Promethazine could be extracted from liver and kidney tissue The boy had also received Halothane and during the post operative night a suppository of Aspirin-Phenacetin-Codein The other deaths were due to various causes but had one factor in common. All of them were bad risk" patients.

Decubitus lesions were encountered in 76 patients. Fortunately only three of them were severe. The great majority of the cases occurred during the first years of application of the technique. At that time we had not yet fully realized that decubitus and local compression are always possible whenever a patient remains immobile for several hours Especially after hypotensive anaesthesia and when lying on the hard, thick rubber pads which our hospitals use to protect their mattresses. Now we pay special attention to the protection of pressure points (see chapter on immediate post-operative measures) and recommend the nursing staff to move the patient slightly every 2 hours.

The lesions encountered were mostly localised in the pericoccygeal area. Treatment consisted of an intravenous infusion of 500 ml Rheomacrodex® with 3 to 4 ml heparin. A four times daily application of Butazolidine® ointment completes this therapy

Local induration of a vein after i v injection of the mixture of drugs was seen in 208 patients.

Dilution of the Pethidine and the rest of the mixture in a sufficient amount of normal saline or glucose 5 makes this minor but undesirable side effect much less frequent. Today we

une circulation centrale et périphérique sans vasoconstriction
une pression veineuse basse et stable.
out cela aussi bien pendant la période post opératoire immédiate que pendant la période opératoire et cela sans transitions brutales. Cet at anesthésique en outre est caractérisé par ne hypotension artérielle, une très bonne cir ulation périphérique et capillaire, ainsi que par une légère hypothermie.

Nous obtenons ainsi un champ opératoire aussi exsangue que possible, ce qui constitue un atout majeur pour des disciplines chirurgicales où la possibilité d'hémostase locale est très limitée la chirurgie O.R.L. (surtout la microchirurgie de l'oreille), la neurochirurgie, la chirurgie ophthalmologique et la chirurgie maxillo-faciale. La période post-opératoire est caractérisée par un réveil progressif et non agité.

La méthode est décrite du point de vue clinique et pratique. Des considérations théoriques ne sont mentionnées que pour expliquer un point particulier de la technique.

Zusammenfassung

Mit der beschriebenen Narkose-Methode wird ein Zustand erreicht, der charakterisiert ist durch eine Analgesie sowie eine tiefe und anhaltende Neurolepsie. Die neurovegetativen Reaktionen sind erheblich reduziert.

Es gibt keine Anzeichen von Atemdepression. Die Atmung ist der eines physiologischen Tiefschlafes vergleichbar daher die Bezeichung überwachter Schlaf" (sommeil protégé).

Wir sind der Meinung, dass dieser besondere Aspekt von grosser Bedeutung ist.
Dies ermöglicht.
— einen konstanten CO_2 Partialdruck
— einen vasokonstriktionsfreien zentralen und peripheren Kreislauf
— einen niedrigen und stabilen Venendruck
und zwar nicht nur während des Eingriffs, sondern auch unmittelbar nach der Operation, ohne scharfe Transitionen zu zeigen. Dieser Narkosezustand ist ausserdem charakterisiert durch eine arterielle Hypotonie, eine sehr gute Peripherie und Kapillardurchblutung, sowie durch eine leichte Hypothermie.

Auf diese Weise verfügen wir über ein möglichst blutleeres Operationsfeld, was einen bedeutenden Vorteil für die chirurgischen Disziplinen darstellt, in den Fällen, wo die lokalen Hämostasemöglichkeiten sehr beschränkt sind. O.R.L.-Chirurgie (vor allem die mikrochirurgischen Eingriffe am Ohr), die Neurochirurgie, die Augenchirurgie und die Oberkiefer-Gesichtschirurgie. Die postoperative Phase ist charakterisiert durch ein allmähliches, ruhiges Erwachen.

Die Methode wird aus klinischer und praktischer Sicht beschrieben. Theoretische Betrachtungen dienen nur zur Erklärung technischer Einzelheiten.

E Patients' Statistics

A total number of 5 628 operations were performed under the described type of anaesthesia, from 1960 until Juli 1969

(1) *Microscopic ear surgery* (age range of patients, 5 to 74 years)

Stapes surgery	1 360	
Reconstructive surgery of the ear (with or without homograft)	1 244	
Surgery of the facial nerve (either through os petrosum or by external approach	45	
Congenital ear atresia	18	2 677

(2) *Neurosurgery* (age range of patients, 18 months to 81 years)
The author used the Protected Sleep" technique of anaesthesia in 765 cases out of a total of 1 914 neurosurgical operations which were performed by Dr P Selosse from 1961 until 1969 In the other cases anaesthesia was administered by a colleague Dr A. Soetens

Cerebral tumours (or similar types of intervention)	272	
Cerebral arterio-venous malformations	12	
Cranial traumata (among others extra- and subdural hematomata)	98	
Operations on the cervical and lower spine (among others, nucleus pulposus surgery)	359	
Miscellaneous (among others trigeminal neuralgia hydrocephaly focal epilepsy cerebral biopsy)	24	765

(3) *Ophthalmic surgery* (age range of patients, 2 to 94 years)

Cataracts	671	
Glaucomas	352	
Corneal grafts	15	
Enucleations (with or without implant)	33	
Retinal detachments	69	
Dacryo-cystorhinostomies	54	
Eyelid plastics	27	
Strabismus	672	
Miscellaneous	16	1 909

(4) *Maxillo-facial and E.N T surgery* (age range of patients, 12 to 78 years)

Maxillar and mandibular tumours	55	
Paradental cysts	30	
Larynx surgery	76	
Thyroid surgery	82	
Parotid surgery	37	
Neck surgery (mostly for tumours)	21	
Vocal cord surgery	3	
Nose and sinus surgery	83	387
	Total	5 628

Résume

La méthode d anesthésie décrite provoque un état caractérisé par une analgésie et une neurolepsie profonde et résiduelle Les réactions neurovégétatives sont sensiblement réduites.

Il n'y a pas de signes de dépression respiratoire. La respiration est *tout à fait comparable* à celle observée chez un sujet en sommeil physiologique au stade profond, d ou la dénomi

sation de « Sommeil Protégé ». Nous estimons que cet aspect particulier est très important. Cela nous permet d'obtenir
— une pCO_2 constante
— une circulation centrale et périphérique sans vasoconstriction
— une pression veineuse basse et stable.

Tout cela aussi bien pendant la période post-opératoire immédiate que pendant la période opératoire et cela sans transitions brutales. Cet état anesthésique en outre est caractérisé par une hypotension artérielle, une très bonne circulation périphérique et capillaire, ainsi que par une légère hypothermie.

Nous obtenons ainsi un champ opératoire aussi exsangue que possible, ce qui constitue un atout majeur pour des disciplines chirurgicales où la possibilité d'hémostase locale est très limitée : la chirurgie O.R.L. (surtout la microchirurgie de l'oreille), la neurochirurgie, la chirurgie ophthalmologique et la chirurgie maxillo-faciale. La période post-opératoire est caractérisée par un réveil progressif et non agité.

La méthode est décrite du point de vue clinique et pratique. Des considérations théoriques ne sont mentionnées que pour expliquer un point particulier de la technique.

Zusammenfassung

Mit der beschriebenen Narkose-Methode wird ein Zustand erreicht, der charakterisiert ist durch eine Analgesie sowie eine tiefe und anhaltende Neurolepsie. Die neurovegetativen Reaktionen sind erheblich reduziert.

Es gibt keine Anzeichen von Atemdepression. Die Atmung ist der eines physiologischen Tiefschlafes vergleichbar: daher die Bezeichnung „überwachter Schlaf" (sommeil protégé).

Wir sind der Meinung, dass dieser besondere Aspekt von grosser Bedeutung ist.
Dies ermöglicht:
— einen konstanten CO_2 Partialdruck
— einen *vasokonstriktionsfreien zentralen und peripheren Kreislauf*
— einen *niedrigen und stabilen* Venendruck

CONTENTS

I Introduction

Hearing loss, ataxia and complaints of vertigo are commonly encountered in old age. Ostensibly these disturbing symptoms, which do not necessarily appear concurrently may be interpreted as suggesting a degenerative process affecting the entire labyrinth. Although age-related cell loss has been demonstrated in the cochlea, corresponding changes within the vestibular portion have not been documented (Weiss, 1959)

The investigation of vestibular function and aging has been undertaken in a rather small number of studies. The diversity of methods employed in these studies impairs one's understanding of what changes, if any may be normally expected as a function of age. For vestibular nystagmus, the most frequently reported age effect has been hypo-reactivity (Arslan, 1957 Brookler & Pulec, 1970 Camarada & Lumia, 1959 Haas, 1964 Minnigerode, Grohmann & Vontin, 1967 Okano, 1938 Rossberg, 1964 Zelenka & Slaninova, 1964). A smaller number of reports have indicated heightened reactivity with age (Chladek, 1966 Guedry 1950 Kotyza, 1939) or no change (Bourhère, 1948 Forgacs, 1957 Fregly & Graybiel, 1970) A review and critique of this literature will follow the presentation of our own results on age and caloric nystagmus, and an attempt will be made to reconcile the various findings into a coherent picture.

II Material and Method

Subjects

The subjects were 293 patients selected from the total sample of 514 patients referred for hearing and vestibular testing primarily due to complaints of dizziness (Table 1). Every attempt was made to exclude subjects demonstrating positive clinical evidence that might contribute to abnormal vestibular function. The appearance of spontaneous or positional nystagmus in the absence of other clinical signs was not considered sufficient basis for exclusion Selection criteria excluded subjects having

1 Positive clinical evidence of pathology (e g Ménière's disease) or injury potentially associated with vestibular dysfunction such as *skull fracture cervical vertigo*, multiple sclerosis, suspected *tumors*, *etc*.

2. Clinically significant unilateral weakness (30–70% asymmetry or greater) based upon the caloric test;

3 *Hearing loss exceeding that of 95% of* subjects of comparable ages surveyed in the U.S. National Health Survey (Glorig & Roberts, 1965)

4 Incomplete data.

Caloric tests

Caloric irrigations of 250 *ml over* 30 sec were performed in the horizontal *supine* position with the head inclined 30 degrees. *Water* temperatures at the syringe tip were 31.5 C (cold) and 44 C (warm) controlled by Labline no. 3057 regulators. *The irrigation* sequence was right ear cold (RC), 5-min rest, left cold (LC) 10-min rest, right warm (RW), 5-min rest, and

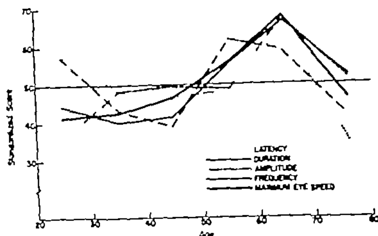

Fig 1 Standard scores ($\bar{X}$ = 50, S D = 10) for nystagmus measures for all four irrigations plotted over age. The latency curve has been inverted for display purposes. The high point for latency for the 60 to 70 group represents decreased or fast latency. The high points for the other measures represent increases.

measure, is adjusted to have a mean of 50 and a standard deviation of 10. As a result, the concordance among the various measures in displaying the age effect becomes *quite clear*. The overall trend is that nystagmus response strength increases to a maximum at 60 to 70 years and declines thereafter. As only four subjects over 80 years of age were tested the final data points do not decline so much as they might have otherwise. Latency and amplitude perturb the shape of the function slightly by manifesting relatively high values for the youngest group. Also amplitude peaks in the 50's instead of the 60's.

The raw score means ($\bar{X}$) and standard deviations (S D) upon which Fig. 1 was based are given in Table _, which provides separate means for the warm and cold irrigations. The male and female nystagmus results were virtually the same and were combined for the means shown in the table. Similarly left-right ear differences were too inconsequential to justify their separate presentation. The data in Table reiterate the tendency for nystagmus responsivity to increase in a roughly regular fashion into the seventh decade (ages 60 to 70). Additionally these data reveal a differential responsivity to the warm and cold stimuli in conjunction with age. The older subjects give disproportionately greater response to the warm irrigations than to the cold.

Significant age-group differences are indicated in Table 2 by superscripts adjacent to the means found to differ by *t*-test comparisons. No significant age differences were observed for latency although latency displayed the same trend as the other measures (Fig. 1). For the cold stimuli, frequency was the only measure to demonstrate significant differences between age groups. For the warm stimuli and the warm and cold combined (total) several significant age differences are shown, particularly for frequency and MES. A few other age-group contrasts were significant at the one tailed level of significance, but these were superfluous to the age differences already evident in Table 2 and are not presented.

The magnitudes of the warm minus cold differences as a function of age are presented in Table 3. The differences in temperature response tend to increase with age in a fairly systematic fashion for duration, amplitude and MES. Between age-group differences on each measure were tested with the *t*-statistic, the outcomes of which are coded in Table 3 by superscripts. In several instances the *t*-test comparisons confirm the significance of the old versus young response differences to the bithermal irrigations.

Fig. displays the age changes for each of the four caloric irrigations using the MES measure. The ordinate scale has been expanded

Table 1 *Age and sex distributions of subjects selected*

Age	Mean age	N Male	Female	Total
20-29	24 6	13	23	36
30-39	35.2	27	32	59
40-49	44 6	34	43	77
50-59	54 6	23	37	60
60-69	64.3	19	23	42
70-88	75 8	6	13	19
		122	171	293

Note Only four subjects were over 80 years old, viz., 83 84 86 and 88. All were females.

left warm (LW) These were conducted in a darkened room with eyes closed while the subject performed distraction arousal tasks (e.g. counting backwards, etc.)

Horizontal eye movement potentials were detected via disc electrodes lateral to the outer canthi referred to a forehead indifferent. The signals were led to a Grass P 6 preamplifier (time constant = 1 7 sec) and written out on a Mingograf 24-B oscillograph. Amplitude of the recording pen height was standardized across subjects by incorporating a 10-degree lateral gaze calibration factor determined prior to the first irrigation Paper speed was 10 mm/sec

Nystagmus measures

Five measures of nystagmus were quantified (1) Latency—time to first beat after start of irrigation (2) Duration—time from first to last nystagmus beat (3) Frequency—number of beats per sec (4) Amplitude—average peak deflection over a series of beats (5) Maximum Eye Speed (MES)—speed of the slow component in degrees per sec = average peak amplitude—average duration of slow component (Coats 1966) For analysis of frequency amplitude and MES, a segment of about 15 beats was selected from the nystagmogram during the period of most intense nystagmus (about 60–90 sec after start of irrigation) Two indices of vestibular symmetry based on MES Unilateral Weakness (UW) and Directional Preponderance (DP) also were calculated (Jongkees, Maas & Philipszoon 1962)

$$\%UW = \frac{(RC+RW)-(LC+LW)}{RC+LC+RW+LW} \times 100$$

$$\%DP = \frac{(LC+RW)-(RC+LW)}{RC+LC+RW+LW} \times 100$$

Unilateral weakness represents the percentage difference between left and right labyrinthine responses. Directional preponderance represents the percentage difference between left and right beating nystagmus from both labyrinths.

Hearing tests

Hearing thresholds were determined for each ear using a *Grason-Stadler E 800 Békésy* Audiometer in an IAC 1201 A room. The attenuation rate was 2.5 dB per sec. Pulsed (2.5 interruptions per sec) and continuous tone thresholds were obtained for the frequency range *125–8 000 Hz, and scored by midpoint* interpolation between the peaks and troughs of the tracings.

III Results

CALORIC NYSTAGMUS AND AGE

Regular changes in vestibular responsivity as a function of age were demonstrated with all five measures of caloric nystagmus (Fig. 1) The data points in this figure are based on the means of all four caloric irrigations. To facilitate comparison, each measure has been standardized (Dixon & Massey 1957) whereby the distribution of scores over all ages for each

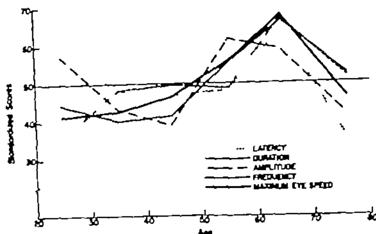

Fig. 1. Standard scores ($\bar{X} = 50$, S.D. = 10) for nystagmus measures for all four irrigations plotted over age. The latency curve has been inverted for display purposes. The high point for latency for the 60 to 70 group represents decreased or fast latency. The high points for the other measures represent increases.

measure, is adjusted to have a mean of 50 and a standard deviation of 10. As a result, the concordance among the various measures in displaying the age effect becomes quite clear. The overall trend is that nystagmus response strength increases to a maximum at 60 to 70 years and declines thereafter. As only four subjects over 80 years of age were tested the final data points do not decline so much as they might have otherwise. Latency and amplitude perturb the shape of the function slightly by manifesting relatively high values for the youngest group. Also, amplitude peaks in the 50's instead of the 60's.

The raw score means ($\bar{X}$) and standard deviations (S.D.) upon which Fig. 1 was based are given in Table 2, which provides separate means for the warm and cold irrigations. The male and female nystagmus results were virtually the same and were combined for the means shown in the table. Similarly left-right ear differences were too inconsequential to justify their separate presentation. The data in Table 2 reiterate the tendency for nystagmus responsivity to increase in a roughly regular fashion into the seventh decade (ages 60 to 70). Additionally these data reveal a differential responsivity to the warm and cold stimuli in conjunction with age. The older subjects give a disproportionately greater response to the warm irrigations than to the cold.

Significant age-group differences are indicated in Table 2 by superscripts adjacent to the means found to differ by *t*-test comparisons. No significant age differences were observed for latency although latency displayed the same trend as the other measures (Fig. 1). For the cold stimuli, frequency was the only measure to demonstrate significant differences between age groups. For the warm stimuli and the warm and cold combined (total) several significant age differences are shown, particularly for frequency and MES_c. A few other age-group contrasts were significant at the one-tailed level of significance, but these were superfluous to the age differences already evident in Table 2 and are not presented.

The magnitudes of the warm minus cold differences as a function of age are presented in Table 3. The differences in temperature response tend to increase with age in a fairly systematic fashion for duration, amplitude and MES_c. Between age-group differences on each measure were tested with the *t*-statistic, the outcomes of which are coded in Table 3 by superscripts. In several instances the *t*-test comparisons confirm the significance of the old versus young response differences to the bithermal irrigations.

Fig. 2 displays the age changes for each of the four caloric irrigations using the MES measure. The ordinate scale has been expanded

Table 1 *Age and sex distributions of subjects selected*

Age	Mean age	*N*		
		Male	Female	Total
20–29	24.6	13	23	36
30–39	35.2	27	32	59
40–49	44 6	34	43	77
50–59	54 6	23	37	60
60–69	64.3	19	23	42
70–88	75 8	6	13	19
		122	171	293

Note Only four subjects were over 80 years old, viz., 83 84 86 and 88. All were females.

left warm (LW) These were conducted in a darkened room with eyes closed while the subject performed distraction-arousal tasks (e.g. counting backwards etc.)

CALORIC NYSTAGMUS AND AGE

Regular changes in vestibular responsivity as a function of age were demonstrated with all five measures of caloric nystagmus (Fig. 1) The data points in this figure are based on the means of all four caloric irrigations. To facilitate comparison each measure has been standardized (Dixon & Massey 1957) whereby the distribution of scores over all ages for each

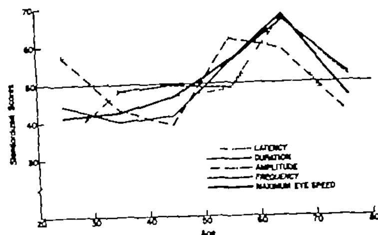

Fig. 1. Standard scores ($\bar{X} = 50$, S.D = 10) for nystagmus measures for all four irrigations plotted over age. The latency curve has been inverted for display purposes. The high point for latency for the 60 to 70 group represents a decreased or fast latency. The high points for the other measures represent increases.

measure, is adjusted to have a mean of 50 and a standard deviation of 10. As a result, the concordance among the various measures in displaying the age effect becomes quite clear. The overall trend is that nystagmus response strength increases to a maximum at 60 to 70 years and declines thereafter. As only four subjects over 80 years of age were tested the final data points do not decline so much as they might have otherwise. Latency and amplitude perturb the shape of the function slightly by manifesting relatively high values for the youngest group. Also, amplitude peaks in the 50's instead of the 60's.

The raw score means ($\bar{X}$) and standard deviations (S.D.) upon which Fig. 1 was based are given in Table 2, which provides separate means for the warm and cold irrigations. The male and female nystagmus results were virtually the same and were combined for the means shown in the table. Similarly left-right ear differences were too inconsequential to justify their separate presentation. The data in Table 2 reiterate the tendency for nystagmus responsivity to increase in a roughly regular fashion into the seventh decade (ages 60 to 70). Additionally these data reveal a differential responsivity to the warm and cold stimuli in conjunction with age. The older subjects give a disproportionately greater response to the warm irrigations than to the cold.

Significant age-group differences are indicated in Table 2 by superscripts adjacent to the means found to differ by t-test comparisons. No significant age differences were observed for latency although latency displayed the same trend as the other measures (Fig. 1). For the cold stimuli, frequency was the only measure to demonstrate significant differences between age groups. For the warm stimuli and the warm and cold combined (total) several significant age differences are shown, particularly for frequency and MES. A few other age-group contrasts were significant at the one tailed level of significance, but these were superfluous to the age differences already evident in Table 2 and are not presented.

The magnitudes of the warm minus cold differences as a function of age are presented in Table 3. The differences in temperature response tend to increase with age in a fairly systematic fashion for duration, amplitude and MES. Between age-group differences on each measure were tested with the t-statistic, the outcomes of which are coded in Table 3 by superscripts. In several instances the t-test comparisons confirm the significance of the old versus young response differences to the bithermal irrigations.

Fig. 2 displays the age changes for each of the four caloric irrigations using the MES measure. The ordinate scale has been expanded

Table I *Age and sex distributions of subjects selected*

Age	Mean age	N Male	Female	Total
20–29	24 6	13	23	36
30–39	35 2	27	32	59
40–49	44 6	34	43	77
50–59	54 6	23	37	60
60–69	64 3	19	23	42
70–88	75 8	6	13	19
		122	171	293

Note Only four subjects were over 80 years old, viz. 83 84 86 and 88. All were females.

left warm (LW) These were conducted in a darkened room with eyes closed while the subject performed distraction arousal tasks (e.g. counting backwards, etc.)

Horizontal eye movement potentials were detected via disc electrodes lateral to the outer canthi referred to a forehead indifferent. The signals were led to a Grass P 6 preamplifier (time constant = 1 7 sec) and written out on a Mingograf 24-B oscillograph Amplitude of the recording pen height was standardized across subjects by incorporating a 10-degree lateral gaze calibration factor determined prior to the first irrigation. Paper speed was 10 mm/sec.

Nystagmus measures

Five measures of nystagmus were quantified (1) Latency—time to first beat after start of irrigation (2) Duration—time from first to last nystagmus beat (3) Frequency—number of beats per sec (4) Amplitude—average peak deflection over a series of beats (5) Maximum Eye Speed (MES)—speed of the slow component in degrees per sec = average peak amplitude − average duration of slow component (Coats 1966). For analysis of frequency amplitude and MES_s, a segment of about 15 beats was selected from the nystagmogram during the period of most intense nystagmus (about 60–90 sec after start of irrigation) Two indices of vestibular symmetry based on MES Unilateral Weakness (UW) and Directional Preponderance (DP) also were calculated (Jongkees, Maas & Philipszoon 1962)

$$\%UW = \frac{(RC + RW) - (LC + LW)}{RC + LC + RW + LW} \times 100$$

$$\%DP = \frac{(LC + RW) - (RC + LW)}{RC + LC + RW + LW} \times 100$$

Unilateral weakness represents the percentage difference between left and right labyrinthine responses Directional preponderance represents the percentage difference between left and right beating nystagmus from both labyrinths.

Hearing tests

Hearing thresholds were determined for each ear using a Grason Stadler E 800 Békésy Audiometer in an IAC 1201 A room. The attenuation rate was 2 5 dB per sec Pulsed (2.5 interruptions per sec) and continuous tone thresholds were obtained for the frequency range 125–8 000 Hz and scored by midpoint interpolation between the peaks and troughs of the tracings.

III Results

CALORIC NYSTAGMUS AND AGE

Regular changes in vestibular responsivity as a function of age were demonstrated with all five measures of caloric nystagmus (Fig. 1) The data points in this figure are based on the means of all four caloric irrigations. To facilitate comparison each measure has been standardized (Dixon & Massey 1957) whereby the distribution of scores over all ages for each

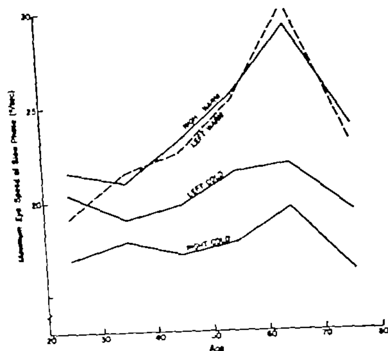

Fig. 2. Raw score means for maximum eye speed of slow nystagmus component plotted over age for each of the four irrigations.

meters (amplitude, frequency and MES_s), Fig. 3 indicates that all age groups tended to give stronger responses to the two warm stimuli than to the cold. Aside from the fact that the older subjects showed a greater warm–cold response difference than the young, which was noted above the present point is that the warm stimuli tended to elicit a greater mean intensity of response than the cold for all our subjects, regardless of age, and this outcome is at odds with some previous reports (Fitzgerald & Hallpike, 1942, and others) To some extent the cold dominance observed by others can be attributed to the corneo-retinal potential shift (Hart, 1969). Regarding the general warm dominance presently observed, however this must in part reflect the unfortunate failure of our apparatus to maintain the cold water bath at less than 31.5 C. The resulting asymmetry being that the cold stimulus was only 5.5 below normal body temperature (37 C), while the warm (44 C) was correctly 7.0 above. A warm dominance in nystagmus intensity would naturally be expected under these circumstances. Preber (1958) and Mehra (1964) however likewise observed a significant MES_s warm dominance (with young adults) using accurately controlled irrigation temperatures (30 and 44 C). While our absolute warm–cold response differences should not be taken at face value, this does not detract from the finding of a progressive increase in the warm–cold response difference up to age 70 The asymmetrical temperatures have presumably only shifted the baseline of the cold response somewhat.

Generalizing from the temperature studies of Henriksson (1956) and Maran (1966) an increment of about 5 /sec in MES_s over the present means for the cold stimuli would have

---

Subsequent to the gathering of the present data the cold water temperature control mechanism was corrected to provide the proper degree of coldness (30°C). T elve new subjects, all over 50 years old, ha e since been tested. Eight of the twelve manifested higher MES in response to the tw warm irrigations compared with the cold, indicating that the warm dominance observed was not an artifact of asymmetrical temperature.

Note Superscripts designate significant ($p < 0.05$ two-tailed) differences between age groups using t-tests. For a given nystagmus measure (e.g. within a row) age group pairs bearing the same superscript letter are significantly different.

in this figure to exaggerate the differences between *warm* and cold *responses*, which we find are shown more dramatically by MES than by any of the other parameters. The warm hyper reactivity of the 50- and 60-year-olds is prominent in this figure. It is apparent that only *minimal changes with age occur for the cold* stimuli. An additional finding shown in Fig. 2 is the greater MES response by all age groups to the left cold irrigation (which is administered second) relative to the right cold (first) This may be due to an intensification of the corneo-retinal potential following the initial cold calorization as documented by Hart (1969) The amount of difference between the right and left cold calorizations appears to undergo no variation as a function of age in Fig. 2 suggesting that corneo-retinal potential shifts, if they occurred were constant over age.

With respect to the nystagmus intensity para-

meters (amplitude, frequency and MES.) Fig. 3 indicates that all age groups tended to give stronger responses to the two warm stimuli than to the cold. Aside from the fact that the older subjects showed a greater warm–cold response difference than the young, which was noted above the present point is that the warm stimuli tended to elicit a greater mean intensity of response than the cold for all our subjects, regardless of age, and this outcome is at odds with some previous reports (Fitzgerald & Hallpike, 1942, and others) To some extent the cold dominance observed by others can be attributed to the corneo-retinal potential shift (Hart, 1969). Regarding the general warm dominance presently observed, however this must in part reflect the unfortunate failure of our apparatus to maintain the cold water bath at less than 31.5 C. The resulting asymmetry being that the cold stimulus was only 5.5 below normal body temperature (37 C) while the warm (44 C) was correctly 7.0 above. A warm dominance in nystagmus *intensity* would naturally be expected under these circumstances. Preber (1958) and Mehra (1964) however likewise observed a significant MES, warm dominance (with young adults) using accurately controlled irrigation temperatures (30 and 44 C). While our absolute warm–cold response differences should not be taken at face value, this does not detract from the finding of a progressive increase in the warm–cold response difference up to age 70. The asymmetrical temperatures have presumably only shifted the baseline of the cold response somewhat.[1]

Generalizing from the temperature studies of Henriksson (1956) and Maran (1966) an increment of about 5 /sec in MES over the present means for the cold stimuli would have

---

[1] Subsequent to the gathering of the present data the cold water temperature control mechanism was corrected to provide the proper degree of coldness (30°C). Twelve new subjects, all over 50 years old, have since been tested. Eight of the twelve manifested higher MES in response to the two warm irrigations compared with the cold, *indicating that* the warm dominance observed was not an artifact of asymmetrical temperature.

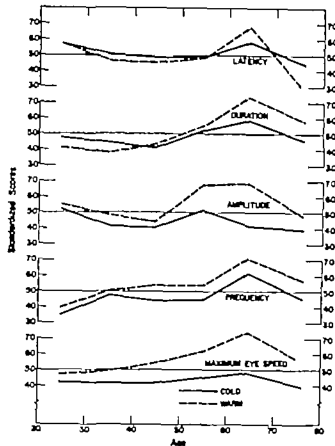

Fig 3 Standard scores for each nystagmus measure plotted over age separately for warm and cold stimuli. The latency curves have been inverted (see Fig. 1 caption).

been observed had the water been 30 rather than 31 5 C Projecting this hypothetical increment onto Fig. 2 produces the inference that our young subjects would have given a stronger MES response to the cold stimuli than to the warm whereas the converse would be true for the 50- and 60-year-olds. Thus, paradoxically the young groups would have shown a response decline" (Stahle, 1956) associated with repeated irrigations, while the middle aged subjects would have shown a response enhancement.

Despite the temperature asymmetry Fig. 3 shows that for latency and duration the young subjects still demonstrated higher scores in response to the cold water compared with the warm. The ability of the cold dominance to override the temperature asymmetry suggests that this response bias is a potent one at least for latency and duration. It is not surprising then that the duration measure has been frequently noted to reflect higher values for cold as opposed to warm irrigations when the cold water was correctly 30 C (Fitzgerald & Hallpike, 1942) In accord with the present results Preber s (1958) and Mehra s (1964) young adults showed significantly longer durations following cold stimulation while showing significantly greater MES following warm. As the cold dominance was seen only in our younger subjects and since relatively young subjects have been typically used in previous studies, it may be that the traditional prolongation of nystagmus following cold stimuli relative to warm does not occur for older subjects. Our results suggest that it does not.

The possibility that the order of administration of the bithermal tests interacts with aging effects must also be considered in the present context. As the warm irrigations are always performed last, it is possible that the aged give a heightened response to them because of some factor associated with repeated testing, to which they are more sensitive than the young. Stahle (1956) varied the caloric test sequence giving one group of subjects the warm calorics first and another group the cold calorics first. He found no important effects of sequence, but age as a variable was not studied. Since the now widely standardized caloric test battery routinely provides the cold irrigations first, the question of age and sequence interaction seems academic.

With regard to response changes following repeated calorics in relation to age Gramowski & Unger (1969) noticed a greater decline (habituation) in 60- to 70-year-old subjects than in 15 to 25-year-olds receiving five cold irrigations at eight minute intervals. All subjects in that study showed some response decline upon repeated testing. From this source we might have anticipated a reduced warm response by our older subjects because the warm calorics were always administered last As the outcome was quite the reverse (i.e enhanced warm response) test repetition can probably be ruled out here as unimportant.

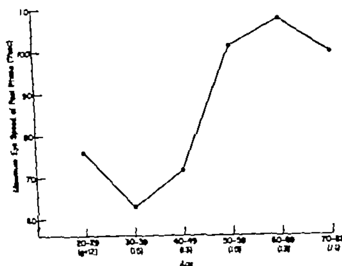

Fig. 4. Raw score mean maximum eye speed of the fast component for the left warm stimulus plotted over age for a subsample of 79 subjects.

FAST PHASE CHANGES

We also examined the speed of the fast phase of nystagmus (MES_f) for age effects. This measure has been previously noted to be insensitive to such manipulations as altering caloric stimulus temperature (Torok & Derbyshire, 1968). MES_f was derived in similar fashion to MES_s, the only difference being that duration of the fast phase was substituted for slow phase duration in the exact method formula (Coats, 1966). As the MES_f measure was not determined routinely for all patients only a subsample was drawn for this purpose.

Fig. 4 presents, for the left warm stimulus, the MES_f age-group means for 79 patients selected at random from our total sample. It is obvious in Fig. 4 that after age 50 the MES_f increases sharply. The significance of the over under 50 difference was confirmed by a Median test (Dixon & Massey 1957). For the cold stimuli, as previously observed for MES_s, age related changes in MES_f were minimal. MES_f and MES_s are not identical reflections of one another however since their intercorrelation was only $r = 0.59$ ($N = 79$). The intensification of nystagmus during middle age can thus be discerned from all measurable aspects of the nystagmogram following warm stimulation.

Table 4. *Asymmetry and spontaneous nystagmus as a function of age*

	Age	20–29 (n = 36)	30–39 (59)	40–49 (77)	50–59 (60)	60–69 (42)	70–88 (19)

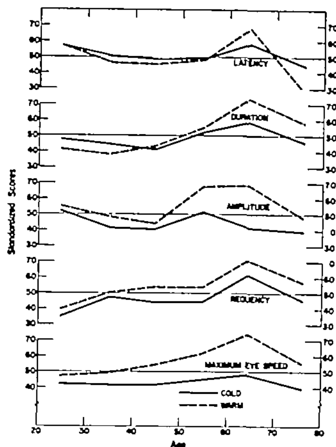

Fig 3 Standard scores for each nystagmus measure plotted over age separately for warm and cold stimuli. The latency curves have been inverted (see Fig. 1 caption).

been observed had the water been 30 rather than 31 5 C Projecting this hypothetical in crement onto Fig. 2 produces the inference that our young subjects would have given a stronger MES response to the cold stimuli than to the warm whereas the converse would be true for the 50- and 60-year-olds. Thus paradox ically the young groups would have shown a response decline" (Stahle 1956) associated with repeated irrigations, while the middle aged subjects would have shown a response enhancement.

Despite the temperature asymmetry Fig. 3 shows that for latency and duration the young subjects still demonstrated higher scores in response to the cold water compared with the warm The ability of the cold dominance to override the temperature asymmetry suggests that this response bias is a potent one, at least for latency and duration. It is not surprising then that the duration measure has been f quently noted to reflect higher values for co as opposed to warm irrigations when the co water was correctly 30 C (Fitzgerald & Ha pike 1942) In accord with the present resul Preber s (1958) and Mehra s (1964) you adults showed significantly longer durations fo lowing cold stimulation while showing signi cantly greater MES following warm. As th cold dominance was seen only in our young subjects and since relatively young subjec have been typically used in previous studie it may be that the traditional prolongation o nystagmus following cold stimuli relative t warm does not occur for older subjects. Ou results suggest that it does not.

The possibility that the order of administra tion of the bithermal tests interacts with agin effects must also be considered in the presen context. As the warm irrigations are alway performed last, it is possible that the aged giv a heightened response to them because of som factor associated with repeated testing, to which they are more sensitive than the young. Stahle (1956) varied the caloric test sequence, giving one group of subjects the warm calorics firs and another group the cold calorics first. He found no important effects of sequence, but age as a variable was not studied Since the now widely standardized caloric test battery rou tinely provides the cold irrigations first, the question of age and sequence interaction seems academic.

With regard to response changes following repeated calorics in relation to age, Gramowski & Unger (1969) noticed a greater decline (habituation) in 60- to 70-year-old subjects than in 15 to 25-year-olds receiving five cold irrigations at eight minute intervals. All subjects in that study showed some response decline upon repeated testing. From this source we might have anticipated a reduced warm response by our older subjects because the warm calorics were always administered last. As the outcome was quite the reverse (i e. enhanced warm re sponse) test repetition can probably be ruled out here as unimportant.

($r \approx 0.50$). High frequency loss increases in orderly fashion with age.

For caloric nystagmus, however the vestibular age changes are not so orderly The youngest (20's) and oldest (70+'s) groups were shown to form "hooks on the ends of some of the curves in Figs. 1 and 3 Such deviations from linearity tend to reduce the size of linear correlation coefficients (Pearson r) computed between age and nystagmus. These coefficients, which are given in Table 5 for each irrigation, were therefore determined omitting the 70+ group. The exclusion had the effect of raising the coefficients slightly as would be expected. In Table 5 the most consistent age nystagmus correlations occur for frequency Duration and MES, also show some significant r s. The significant age MES correlations under the warm conditions appear associated with the small positive r s demonstrated by amplitude. (MES is computationally dependent on amplitude.) The rises in MES, and amplitude under the warm conditions were also illustrated by the curves for the 50- and 60-year-olds in Fig. 3

Table 5 *Intercorrelations between age and nystagmus measures for each irrigation*

	RC	LC	RW	LW
Latency	−.01	.01	−.03	−.04
Duration	.16	.11	.19	.17
Amplitude	−.02	−.02	.09	10
Frequency	.24	.21	.23	17
MES_v	.08	.07	19	.27

Note: Age 70+ group omitted. Significant ($p < 0.05$) r coefficients are indicated by asterisks.

Intercorrelations were then computed between the nystagmus measures and hearing thresholds, with the 70+ group omitted. Since both nystagmus frequency and hearing loss were known to correlate with age, the age effect was held constant via the partial correlation technique (Hays, 1963) As a consequence, the hearing-nystagmus intercorrelations vanished in all but one instance For the male subjects only at tone frequencies at and above 2 kHz, small but significant partial correlation coefficients ($r \approx .20$) remained between hearing threshold and nystagmus frequency as well as MES_v, with age held constant. The positive sign of these coefficients indicated that the greater the high frequency hearing loss, the greater the frequency and MES of caloric nystagmus (for males up to 70 years old) for both warm and cold stimuli.

This finding was examined more closely by comparing subjects showing the most bilateral high frequency hearing loss (2 kHz − 8 kHz) with those showing the least, with respect to MES_v. This was performed separately for males and females of all ages up to 70 years old. The most- and least-loss subgroups were matched for age, with their n s determined by the number of subjects available with sufficient hearing loss. Table 6 gives the mean MES_v of all four irrigations and mean hearing threshold levels at 2 kHz − 8 kHz for the selected male subjects. It is evident in Table 6 that males with high frequency loss tend to show greater MES than no-loss males. This difference was significant for all ages combined ($t = 2.28$ $p < .05$). MES shows roughly a 5 / sec increase for the poor hearing subjects over 50 years old relative to those under 50 Very little such increase is apparent for the normal-hearing men. High frequency hearing loss appears associated with intensified nystagmus for men of all ages up to 70. The corresponding analysis done for females revealed no significant most–least hearing differences in MES_v (These data are not tabulated here.) However the females degree of hearing loss was clearly much less than that of the males. The pattern of severe high frequency hearing loss and intensified nystagmus among males may *represent* a characteristic sex difference.

The associated change in hearing and nystagmus shown by men with high frequency hearing loss implies a deteriorative effect common to both cochlear and vestibular end organs not dependent upon age. If we assume that the high frequency hearing losses observed were solely the result of acoustic trauma (noise) this leads to the speculation that acoustic trauma,

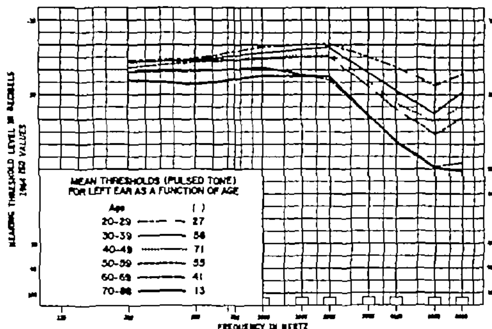

Fig 5 Mean Békésy pulsed-tone thresholds (left ear) *for each of the six age* groups. Some *N*s are reduced due to missing audiograms.

SYMMETRY AND SPONTANEOUS NYSTAGMUS

Table 4 gives the mean values for unilateral weakness (*UW*) and *directional preponderance* (DP) as well as as the incidence of spontaneous and positional nystagmus for each age group There are no systematic differences in UW or DP as a function of age The formulae for UW and DP (see under Method) are such that the negative UW values shown in Table 4 indicate a right side weakness for all age groups while positive DP values *(preponderance to the* right) occur for all but the 60-year-olds. This *consistent right asymmetry may* be attributed to the heightened nystagmus response provoked by the second cold irrigation (LC) relative to the first (RC) as was illustrated in Fig. 2 Applying the formula for DP the enhanced response to the left cold irrigation has the effect of inflating the right beating nystagmus score, yielding a right DP At the same time for UW the left side total score (LC + LW) becomes inflated yielding a right weakness. As mentioned earlier this rise has been explained by Hart (1969) as *due to a shift in* the corneo-retinal potential following the first irrigation. Since the responses to the two warm irrigations did not differ (Fig. 2) they had no effect on the *asymmetry measures*.

Table 4 also gives the percentage of subjects in each age group manifesting spontaneous or positional nystagmus as defined by Coats (1966) There are no differences among the various age groups in these percentages. The incidence of spontaneous ($\bar{X} = 37\%$) and positional ($\bar{X} = 30\%$) nystagmus observed in this sample is in reasonable agreement with the incidence (36% and 35% respectively) reported by Coats (1966) for similar subjects. In 64% of our subjects manifesting spontaneous nystagmus the quick phase direction was to the right. This would account in part for the right DP tendency observed (cf Coats, 1966)

INTERCORRELATIONS HEARING CALORIC NYSTAGMUS AND AGE

The Békésy hearing thresholds of our patients are plotted as a function of age in Fig. 5 revealing the traditional decline *in high fre*quency hearing acuity with age (presbycusis) Correlation coefficients computed between hearing thresholds and age indicated the highest coefficients to be at 6 kHz and 8 kHz

Table 7 *Intercorrelations among measures of nystagmus for cold and warm irrigations*

	W				.514

Note: Nonsignificant *r*'s are indicated by asterisks. All others were significant ($p < 0.05$).

coefficients obtained between frequency and amplitude. Accordingly as frequency increases amplitude tends to decrease, and vice versa. Frequency and to a minor extent, amplitude were previously noted to increase slightly with age up to the 70's, at least for the warm stimuli. But the possibility of both measures increasing is obviously limited due to the reciprocal condition mentioned.

Table 7 indicates some degree of independence from the other measures for the frequency parameter. Latency and duration are not at all correlated with frequency although they are mildly correlated with amplitude and MES_v. And while frequency is intercorrelated with amplitude and MES_v, the magnitude of the coefficients varies from cold to warm. The latter fact could reflect changes in the central control of the interaction between slow and fast phases as a function of stimulus temperature. The cold and warm irrigations may engage slightly different reflex arrangements mediating the rhythmic balance between slow and fast components. Torok (1969) found that the correlation between frequency and MES_v decreased as caloric temperature was reduced from 30 to 10 C. It would be of interest to determine if a similar divergence occurs for varying degrees of hotness.

IV Literature Review and Critique

In retrospect, it appears clearly possible to assemble most of the earlier studies, which at first appeared quite diverse in their outcomes, and reconcile their findings into accord with the picture developed by the present data. The key to reconciling the various findings lies chiefly with how the subjects were grouped by age and what age range was investigated. Shortcomings in data analysis appeared a frequent problem while variations among techniques of vestibular testing seemed relatively unimportant.

The present and the previous studies have employed exclusively the cross-sectional approach to studying age effects on vestibular function. In this approach, groups of subjects born at different times are compared. To date, no studies in this area have used a longitudinal design, wherein individuals are compared with themselves as they age. An unavoidable problem associated with cross-sectional studies is that differences may exist between populations of subjects born at different times which are attributable to factors other than the aging process. Thus in the present study where we compare subjects born in 1950 with those born in 1900, we must recognize that many differences may exist between the two age groups with respect to their different life experiences (e.g., diet,

Table 6. *Mean MES and hearing levels (2k–8kHz) of males selected for least high frequency hearing loss*

	Age groups				
Hearing loss	20–39 (n=24)	40–49 (20)	50–59 (14)	60–69 (12)	All (70)
MES$_s$					
Most	20.40	19 61	25.97	26.80	22.39
Least	15 47	19.33	19.37	18.32	17 84
Hearing levels (dB)					
Most	38.9	47.5	45 8	64.5	47 1
Least	8.2	10.2	20.0	35 4	15 8

Note Age group *N*'s should be divided by two to find Most or Least subgroup *n* s. The 20 s and 30's were combined due to a small number of 20's having hearing loss.

which is relatively uncommon in women can bring about degenerative changes in the vestibular apparatus as well as the cochlea. In an earlier study on lateralization to be described below we similarly noticed vestibular hearing relations among men with high frequency hearing losses (Bruner & Norris, 1970) However the assumption that high frequency hearing loss is produced solely by unusual noise exposure may not always be warranted since similar audiograms are often associated with acute inner ear infections, presumably viral (D E Kilgore M D Lovelace Clinic, personal communication) In such a case, ordinary noise levels may be able to induce transient or permanent high frequency loss in the vulnerable cochlea.

Except for the association between high frequency loss and nystagmus intensity in men no further relations could be established between hearing and nystagmus in the total sample This included an analysis of threshold differences between continuous and pulsed tones. In Ménière s patients, Enander & Stahle (1969) have reported that a large continuous pulsed separation is associated with caloric hyporeactivity In the present study the separation between continuous and pulsed tracings tended to increase with age at the high frequencies But the separation was not correlated with nystagmus intensity when the age influence was held constant.

In a previous study (Bruner & Norris, 1971) involving test pilots and patients presenting Békésy audiograms indicative of unilateral acoustic trauma (i.e. a high frequency notch) we obtained a significant correlation between the extent of bilateral hearing threshold differences and caloric DP where the direction of preponderance was toward the worse hearing ear at high frequencies. The lateralization of DP and hearing loss was not evident in patients having wideband unilateral hearing loss or in normals with bilaterally symmetrical hearing acuity In the current heterogeneous sample of patients, no correlation was found between DP and unilateral high frequency loss. Thus, the impression is continued from the earlier study that a unilateral acoustic trauma type audiogram may be essential for the lateralization effect to appear But as discussed above, a history of severe noise exposure may not be essential for this phenomenon.

INTERCORRELATIONS BETWEEN NYSTAGMUS MEASURES

The intercorrelations between the several nystagmus measures are presented in Table 7 for both cold and warm stimuli. Latency and duration are moderately intercorrelated indicating that subjects having brief latencies tended to show prolonged durations Subjects having brief latencies and long durations also tended to have high amplitudes and high MES although the degree of association is minor

Frequency and amplitude are intercorrelated positively with MES$_s$ that is, as either of the former increases so does MES$_s$. This is a necessary outcome from the manner of deriving MES$_s$ which incorporates both amplitude and beat duration (= reciprocal frequency) These three parameters are viewed as indices of nystagmus intensity or vigor But the nystagmus jerk which terminates each complete beat cycle must, at the same time limit the extent of slow phase travel (amplitude) This reciprocal relation is illustrated in the intercorrelation matrix (Table 7) by the negative signs of the small

jects in each age group was not specified, only that a total of 89 subjects was divided into five groups (ages 0–10 10–20, 20–30 30–40 and 40–70). The oldest group (40 to 70) presumably included only about 18 subjects. From the present study we would expect that both high and low points of nystagmus strength could occur within the 40 to 70 group of Minnigerode et al., however their grouping procedure would obfuscate the possibility of such a finding. Furthermore, inspection of the data curves reveals that the oldest group demonstrated slightly greater mean scores for nystagmus duration, amplitude, and number of beats than the 30- to 40-year-olds. Thus the authors claim of a systematic response diminution with age seems questionable, since some indications of a middle-old-age peak were found.

Haas (1964) claimed to have found increased mean rotatory thresholds for normal subjects between 51 and 80 years of age relative to 15- to 50-year-olds. When grouped in this manner the data support the claim, but again grouping obscures precision. Where Haas data are presented in decade form they indicate that the 41–50 group yielded the most sensitive thresholds of all groups, whereas the 51–60 group appears to have even higher thresholds than subjects over 60 To complicate matters further some of Haas age decades contained fewer than 10 subjects, which severely jeopardizes the reliability of his group means.

Camarada & Lumia (1959) used rotational stimuli to assess vestibular sensitivity in 23 subjects aged 70 to 92 years. They found higher thresholds than those considered normal for young subjects. This loss of vestibular excitability in very old people is consistent with most other findings. But it is important to note that age effects as shown by tests of vestibular excitability (rotational or caloric thresholds) may not necessarily follow the same time course of change as when testing responsivity (nystagmus duration, intensity etc.). Thus it is not inconceivable that middle-aged subjects may require relatively strong stimuli to elicit nystagmus initially yet respond with hyperactive nystagmus once the threshold has been surpassed.

Okano (1938) tested 223 healthy subjects ranging in age from the 60's through the 80's using both rotational and caloric stimuli. Nystagmus duration and number of beats decreased gradually with age, and latency tended to increase. Okano s results are in accord with most others in finding a vestibular response decrement after the seventh decade.

Brookler & Pulec (1970) observed a decrease in MES, with age using cold irrigations, but no change using warm. Their curve for the right warm stimulus indicates, however that beginning with the 20-year-olds, MES increased gradually to a peak at the 65- to 74-year age group. The curve then declines for the 80's before rising again for the 90's. (The 90-year data point is probably unreliable since it is based on only six subjects.) The gradual increase in MES up to the 70's for the right warm stimulus displays the same function as seen in the current study Furthermore, the curve drawn by Brookler & Pulec would have been steeper and possibly significant, had they employed the exact method for determining MES (Coats, 1966) instead of their approximate method (measuring fast phase amplitude) which underestimates the exact method by about 20% (Stahle, 1956 Henriksson, 1956). Thus at least for one of their warm irrigations, Brookler & Pulec witnessed results similar to our own.

Brookler & Pulec's (1970) decreasing responsivity with age for the cold stimuli may be a result of including patients with known pathology into their sample. Apparently over 80% of Brookler & Pulec s sample fell into one or more diagnostic categories, including Ménière s disease (16 4%). Although an age distribution for each diagnostic category was not provided, it is probably safe to assume that the incidence of pathology increased with age. As labyrinthine pathology is usually evidenced by caloric hypoactivity from one or both ears (e.g., Fig. 2 of Brookler & Pulec, 1970), the inclusion of a substantial proportion of pathologies would

The principal aging effects reported in the literature appeared to fall conveniently into three classifications (1) Hypo-reactivity (2) Hyper-reactivity or (3) no change with age. The studies will be reviewed in terms of these three categories for ease of presentation, recognizing that some of the studies may actually have observed (or overlooked) an increase followed by a decrease in nystagmus responsivity with increasing age.

Hypo-reactivity with age

Arslan (1957) evaluated vestibular reactions in a group of 50 non-vertigo patients ranging in age from 49 through 84 years using Viet s method of cold water stimulation. For nystagmus duration and number of beats 30 of the 50 patients scores fell below one standard deviation of a norm group of 100 healthy 20-year-olds tested earlier (Arslan, 1955) The author concluded that a shift toward vestibular hypo-excitability"[1] occurs in the elderly

Further study of Arslan s data (1955 1957) suggests that his conclusion requires some qualification. Thirty-one of the 50 subjects in Arslan s old group were over 70 years of age These 31 people manifested low nystagmus scores which had the effect of depressing the means for the entire group below those of the 20-year-olds. When Arslan s 50- and 60-year olds are considered separately their means for number of beats ($\bar{X} = 109.0$ and 106.5 respectively) are larger than the mean of the 20-year olds ($\bar{X} = 94.4$) Thus in agreement with the current findings, Arslan s middle-aged subjects appear hyper reactive relative to the 20-year olds. His conclusion of "hypo-excitability for number of beats applies correctly only for his subjects over 70 years of age For the duration measure Arslan s young group did manifest higher values than his old group But aside from the age-grouping problem here, it has been found previously that, in contrast to older subjects the young may respond with longer durations to cold stimulation yet respond with weaker intensities to warm (Preber 1958 Mehra, 1964)

Zelenka & Slaninova (1964) concluded that the senile vestibular apparatus has a diminished reactivity to rotational as well as caloric stimulation. Tested were 396 healthy subjects ranging in age from 5 to 79 years. From Zelenka & Slaninova s tabulated data it is apparent that after about 20 years of age the nystagmus responses (latency duration threshold and MES,) began to intensify with age attaining maximum reactivity in the 40 s and 50 s for both types of test stimulation. After age 60 responsivity tended to decline, which presumably was the basis for their conclusion of senile hypo-reactivity

Rossberg (1964) using rotational stimuli in three groups of healthy subjects (20–40 41–60 and 61–80 years of age) observed decreases with age in nystagmus amplitude, number of beats and to a lesser extent, duration. This outcome is contradictory to the present findings. Rossberg s three age groups each spanned 20 years and each contained only 20 subjects. His broad grouping and small *n* s preclude evaluation of fine age differences. For example, one cannot determine how many of the 61 to 80-year-old subjects were over 70 We can only suggest that the reliability of Rossberg s observations be verified by additional studies using his technique (cupulometry)

Minnigerode Grohmann & Vontin (1967) noted that amplitude of postrotational nystagmus decreased systematically with age in 89 healthy subjects, ranging from under 10 to 70 years of age. Nystagmus duration and number of beats also tended to decrease, but with less regularity Unfortunately the number of sub-

———

quality of medical care, attitudes toward exercise etc.) associated with cultural change plus possible genetic changes, which will inevitably confound the pure effects of age. Analogous difficulties accompany purely longitudinal designs. Both approaches require sophisticated design and analysis to separate out the age factor (Schaie, 1965 Wohlwill 1970)

[1] The term excitability is not quite appropriate to describe measures of response strength such as number of beats or duration. Excitability implies threshold sensitivity or ease of response elicitation rather than intensity of response to suprathreshold stimuli Better terms for the latter are reactivity or responsivity

jects in each age group was not specified, only that a total of 89 subjects was divided into five groups (ages 0–10 10–20 20–30, 30–40 and 40–70). The oldest group (40 to 70) presumably included only about 18 subjects. From the present study we would expect that both high and low points of nystagmus strength could occur within the 40 to 70 group of Minnigerode et al., however their grouping procedure would obfuscate the possibility of such a finding. Thus the authors claim of a systematic response diminution with age seems questionable, since some indications of a middle-old-age peak were found.

Haas (1964) claimed to have found increased mean rotatory thresholds for normal subjects between 51 and 80 years of age relative to 15- to 50-year-olds. When grouped in this manner the data support the claim, but again grouping obscures precision. Where Haas data are presented in decade form they indicate that the 41 50 group yielded the most sensitive thresholds of all groups, whereas the 51–60 group appears to have even higher thresholds than subjects over 60. To complicate matters further some of Haas age decades contained fewer than 10 subjects, which severely jeopardizes the reliability of his group means.

Camarada & Lumia (1959) used rotational stimuli to assess vestibular sensitivity in 23 subjects aged 70 to 92 years. They found higher thresholds than those considered normal for young subjects. This loss of vestibular excitability in very old people is consistent with most other findings. But it is important to note that age effects as shown by tests of vestibular excitability (rotational or caloric thresholds) may not necessarily follow the same time course of change as when testing responsivity (nystagmus duration, intensity etc.) Thus it is not inconceivable that middle-aged subjects may require relatively strong stimuli to elicit nystagmus initially yet respond with hyperactive nystagmus once the threshold has been surpassed.

Okano (1938) tested 223 healthy subjects ranging in age from the 60's through the 80's using both rotational and caloric stimuli. Nystagmus duration and number of beats decreased gradually with age, and latency tended to increase. Okano's results are in accord with most others in finding a vestibular response decrement after the seventh decade.

Brookler & Pulec (1970) observed a decrease in MES with age using cold irrigations, but no change using warm. Their curve for the right warm stimulus indicates, however that beginning with the 20-year-olds, MES increased gradually to a peak at the 65- to 74-year age group. The curve then declines for the 80's before rising again for the 90's. (The 90-year data point is probably unreliable since it is based on only six subjects.) The gradual increase in MES up to the 70's for the right warm stimulus displays the same function as seen in the current study Furthermore, the curve drawn by Brookler & Pulec would have been steeper and possibly significant, had they employed the exact method for determining MES (Coats, 1966) instead of their approximate method (measuring fast phase amplitude), which underestimates the exact method by about 20% (Stahle, 1956, Henriksson, 1956). Thus at least for one of their warm irrigations, Brookler & Pulec witnessed results similar to our own.

Brookler & Pulec's (1970) decreasing responsivity with age for the cold stimuli may be a result of including patients with known pathology into their sample. Apparently over 80% of Brookler & Pulec's sample fell into one or more diagnostic categories, including Ménière's disease (16.4%). Although an age distribution for each diagnostic category was not provided, it is probably safe to assume that the incidence of pathology increased with age. As labyrinthine pathology is usually evidenced by caloric hypoactivity from one or both ears (e.g., Fig. 2 of Brookler & Pulec, 1970) the inclusion of a substantial proportion of pathologies would

tend to reduce the mean level of nystagmus response strength in conjunction with age. Unfortunately Brookler & Pulec did not present a separate analysis of age effects for their 839 patients considered free of neuro-otologic disease. While Brookler & Pulec s aging findings (i.e. hyporeactivity) may be representative of the total, unscreened patient population seen in an ENT clinic, we suggest that our own findings (i.e. peak hyper reactivity) are more typical for patients relatively free of pathology

Hyper-reactivity with age

Kotyza (1939) studied vestibular function in 117 healthy subjects between the ages of 11 and 63 years, using both rotational and caloric stimuli. With the rotational stimulus, nystagmus duration and number of beats increased up to 45 years of age and then declined slightly in older subjects Using Kobrak s minimal cold caloric test, the number of beats was observed to increase up to age 50 and decline thereafter while latency and duration showed little change The author concluded that the labyrinth is most responsive in the fifth decade. In addition to his finding of peak responsivity in the middle decades, Kotyza s caloric results are similar to our own in that frequency was the parameter most sensitive to age influences using cold stimuli

Guedry (1950) determined the duration of subjective movement sensations following rotation in two groups of 24 subjects each One group ranged in age from 19 to 21 years, and the other from 30 to 53 years. The older group s response indicated a significantly longer duration of perceived movement. This result indicates heightened vestibular effects for Guedry s older subjects which agrees with the present view As one of several possible explanations for his finding, Guedry conjectured that older subjects may have less central control over the vestibular reflex system" (p 3) This notion will be discussed at length later in the present

Chladek (rotational and cold caloric test. tion of 51 hearing-loss patients aged 60 to 75 The author s summary claimed that suprathreshold post rotational excitability was frequently raised the caloric reaction was, however reduced." Chladek compared his results with control data apparently borrowed from Zelenka although no specific reference to a published source of Zelenka s data was cited (Both men were affiliated with the same institution.) No statistical tests were mentioned. When compared with Zelenka s control data Chladek s subjects reveal prolonged durations of post rotational nystagmus, in support of the first claim in his summary With respect to the caloric results, however the proximity of the means of the experimental and control groups and the large size of the standard deviations suggest no significant differences.

In comparison with some normative data published earlier by Zelenka & Slaninova (1964) Chladek's (1966) subjects do indeed reveal prolonged post rotational durations. The caloric results do not, however appear re duced" But this may simply point up the inherent difficulties in trying to compare accurately the data of different investigators. In sum there is some indication that Chladek s subjects revealed post rotational hyper reactivity but none that their caloric responses were hyporeactive. As Chladek sampled only old subjects, about half of whom had severe hearing losses, his findings hold limited value for the present purposes.

Gramowski & Unger (1969) compared a group of 10 normal males between 15 and 25 years old with eight men between 60 and 70 for age differences in habituation to cold calorics Five irrigations of 30 C water were administered at eight minute intervals to the right ear On all measures of nystagmus the old group showed greater habituatory decrement (i.e response decline from first to last irrigation) than the young group *Additionally the* older men manifested longer nystagmus durations. The authors interpreted these observations to mean that active, youthful subjects exhibit some level of habituation even prior to

experimental stimulation. As a consequence of aging, this pre habituation supposedly dwindles, resulting in heightened initial response levels and greater response declines. A lessening of central inhibition would seem the likely neural correlate of this process.

Most important for the present findings is the fact that Gramowski & Unger's 60- to 70-year-olds yielded longer nystagmus durations than the young on every irrigation, most of all on the first one. Unfortunately except for the duration scores, the age-group differences for the other nystagmus measures were not given.

No change with age

Bourlière (1948) tested 160 women ranging in age from 20 to 84 years, using galvanic stimulation to elicit head movements. He concluded that vestibular excitability is not affected by age. However Weiss (1959) performed *t*-tests on Bourlière's published data and found significant between-group differences indicative of vestibular hypo-excitability after the sixth decade. Further inspection of Bourlière's tabulated data reveals that vestibular excitability was slightly higher in the fifth and sixth decades than the fourth, suggesting a two-phased aging function similar to that seen in the present study wherein vestibular responsivity peaks in middle age.

Forgacs (1957) tested 80 nursing home residents over 55 years of age using both rotational and caloric threshold tests. He reported "normal" vestibular reactions in all cases. Forgacs admitted, however that since no normative data were available for comparison with his aged group his conclusion of normality would have to remain tentative until additional subjects could be tested. No subsequent work on this topic by Forgacs was found.

Fregly & Graybiel (1970) administered threshold caloric tests to 76 vertiginous patients ranging in age from 20 to 72 years. The authors mentioned that caloric threshold levels were independent of age although no specific analysis was described. As Fregly & Graybiel's study was not specifically designed to investigate aging, the sample size and age distribution were rather inadequate to determine age effects.

Nystagmus tests in children

Zelenka & Slaninova (1964) examined children using caloric and rotatory techniques in an extensive aging study the adult results of which have already been described. Their sample included 12 children between 5 and 10 years old, 55 between 11 and 15 and 32 young people from 16 to 20 years. According to the authors, the two youngest groups yielded results clearly indicative of "hyporeflexia" relative to adults, particularly for children over seven years of age. Response stabilization and the transition to a normal adult record took place at about age 18. As mentioned earlier the adult age changes observed by Zelenka & Slaninova (1964) revealed an increase in nystagmus to peak reactivity in the middle decades followed by a decline after age 60 Very similar caloric and rotatory findings were obtained for adults by Kotyza (1939), who likewise reported relatively hypo-reactive scores for teenagers.

Young children were also tested by Tibbling (1969) who found that amplitude and eye speed of rotatory nystagmus were most intense in very young children and tended to decrease with age up to 15 years, which was the oldest age studied. The older children in Tibbling's sample presumably correspond to the children over seven years old in Zelenka & Slaninova's sample who were considered hyporeflexive. From these studies and the present one, it appears that the shape of the complete age function for vestibular reactivity is complex. Beginning with infants and young children, the curve reveals hyper-reactivity then decreases to a low point in the second decade, followed by an increase to peak responsivity in the middle decades, and finally depicting hypo-reactivity again in old age—another instance where senility recapitulates childhood.

tend to reduce the mean level of nystagmus response strength in conjunction with age. Unfortunately Brookler & Pulec did not present a separate analysis of age effects for their 839 patients considered free of neuro-otologic disease While Brookler & Pulec s aging findings (i.e. hyporeactivity) may be representative of the *total unscreened patient population* seen in an ENT clinic we suggest that our own findings (i e. peak hyper reactivity) are more typical for patients relatively free of pathology

Hyper reactivity with age

Kotyza (1939) studied vestibular function in 117 healthy subjects between the ages of 11 and 63 years, using both rotational and caloric stimuli. With the rotational stimulus nystagmus duration and number of beats increased up to 45 years of age and then declined slightly in older subjects Using Kobrak s minimal cold caloric test the number of beats was observed to increase up to age 50 and decline thereafter while latency and duration showed little change The author concluded that the labyrinth is most responsive in the fifth decade In addition to his finding of peak responsivity in the middle decades, Kotyza s caloric results are similar to our own in that frequency was *the parameter most sensitive to age influences* using cold stimuli

Guedry (1950) determined the duration of subjective movement sensations following rotation in two groups of 24 subjects each. One group ranged in age from 19 to 21 years and the other from 30 to 53 years. The older group s response indicated a significantly longer duration of perceived movement. This result indicates heightened vestibular effects for Guedry's older subjects which agrees with the present view As one of several possible explanations for his finding, Guedry conjectured that older subjects may have less central control over the vestibular reflex system" (p 3) This notion will be discussed at length later in the present paper

Chladek (1966) employed rotational and cold caloric tests in the examination of 51 hearing-loss patients aged 60 to 75 The author s summary claimed that suprathreshold post rotational excitability was frequently raised the caloric reaction was however reduced." Chladek compared his results with control data apparently borrowed from Zelenka, although no specific reference to a published source of Zelenka s data was cited (Both men were affiliated with the same institution.) No statistical tests were mentioned. When compared with Zelenka s control data, Chladek s subjects reveal prolonged durations of post rotational nystagmus in support of the first claim in his summary With respect to the caloric results, however the proximity of the means of the experimental and control groups and the large size of the standard deviations suggest no significant differences.

In comparison with some normative data published earlier by Zelenka & Slanmova (1964) Chladek s (1966) subjects do indeed reveal prolonged post rotational durations. The caloric results do not however appear reduced" But this may simply point up the inherent difficulties in trying to compare accurately the data of different investigators. In sum there is some indication that Chladek s subjects revealed post rotational hyper reactivity but *none that their caloric responses* were hyporeactive. As Chladek sampled only old subjects, about half of whom had severe hearing losses, his findings hold limited value for the present purposes.

Gramowski & Unger (1969) compared a group of 10 normal males between 15 and 25 years old with eight men between 60 and 70 for age differences in habituation to cold calorics. Five irrigations of 30 C water were administered at eight minute intervals to the right ear *On all measures of nystagmus* the old group showed greater habituatory decrement (i.e response decline from first to last irrigation) than the young group Additionally the *older men manifested* longer nystagmus durations. The authors interpreted these observations to mean that active, youthful subjects exhibit some level of habituation even prior to

Wright, 1967). When subjects are allowed to become drowsy or inattentive, nystagmus may vanish for periods of time following caloric stimulation. Mental alertness tasks tend to eliminate these periods of "suppression" From the concept of inhibitory release, one might predict that suppression is less likely to occur in middle aged subjects than in the young. This could easily be tested by employing mental tasks as the independent variable with old and young subjects.

In addition to inhibitory changes we also have much evidence that aging results in the depression of neural activities characterized mainly by excitation. Sensory thresholds (e.g., hearing levels) are perhaps the prime example. Therefore, when neural systems are classified simply as either excitatory or inhibitory an age-related failure in function may be manifested by superficially opposite effects excitatory activities will be depressed while inhibitory activities will be released.

The notion of a loss of central inhibitory control as the basis for heightened vestibular responsivity associated with either lesions or aging accommodates well to the data. However it can be verified only by corroborating neurophysiological and anatomical evidence, and this is lacking. In the present case we cannot say whether we have observed a central or an end organ effect, or both. The observed changes could be equally well attributed to the labyrinth or to the brain stem (or higher) as both slow and fast components of nystagmus were *affected*.

An obvious etiology for age related changes in vestibular function, whether central or peripheral, would be *vascular insufficiency* an ever present developmental disorder to which the labyrinth is especially prone. Along these lines an early precedent exists for the present findings in the work of Pallestrini (1933) and Scoden (1947), who proposed an explanation based on arteriosclerotic changes To quote from Arslan (1957):

> *Pallestrini* divided arteriosclerosis of the labyrinth into stages: the stage of angioneurosis and that of angiosclerosis. Thus *Scoderi* and *Pallestrini* found in the majority of cases of old subjects belonging to the angioneurotic stage, an increase of vestibular reflexes, above all on thermal stimulation, which is manifested by shortening of the latency period and an increase in the strength of the nystagmic jerk. In the angiosclerotic stage, however a decrease of vestibular reflexes is always found, which is revealed with the lengthening of the latency period and the shorter duration and amplitude of the nystagmic jerk (p. 477).

Zelenka & Kozak (1963) examined 152 patients presenting varying stages of hypertensive and sclerotic disease, ranging from vasospasm ("angioneurosis") to frank arteriosclerosis. All tended to show post-rotatory hyper-reactivity The vestibular neurons which suffer earliest from the ischemia of age and disease appear to be those mediating inhibitory activities.

Local vascular influences

Jongkees (1948) succeeded in reducing nystagmus duration following cold stimulation by local administration of a vasodilator (amyl nitrite) to counteract vasoconstriction. Appropriately the drug had no effect on the hot response since dilation was presumably already maximal. Jongkees further confirmed the importance of local vascular influences on the caloric response with demonstrations of the vasoconstrictive effects of procaine hydrochloride.

The possible involvement of local vascular influences could be a further basis underlying the differences obtained between our middle aged and young subjects. Assume that with age there is a gradual diminution in blood flow to the labyrinth due to vascular narrowing. Applying hot water brings about vasodilation and an improved blood supply which elevates the neural discharge of the stimulated ampulla over that resulting solely *from* cupular bending. It is proposed that the vasodilatory action is more marked in the middle aged ear where the vessels are partially narrowed, than in the young ear where they are fully patent. We are therefore suggesting that the hot caloric *is* in effect a stronger stimulus for middle-aged subjects than for young ones. In the instance of

V Comment and Conjecture

Fourteen studies designed chiefly to investigate the effects of aging on vestibular reactivity have been reviewed and evaluated with reference to the present observations. Nine of these reports we interpret to be in accord or at least not inconsistent, with the current conception of peak responsivity in middle age followed by hypo-reactivity in senility viz. Arslan (1957) Bourlière (1948) Camarada & Lumia (1959) Chladek (1966) Gramowski & Unger (1969) Guedry (1950) Kotyza (1939) Okano (1938) and Zelenka & Slaninova (1964) Of the five remaining studies which did not afford ready concordance those of Haas (1964) Minnigerode Grohmann & Vontin (1967) and Rossberg (1964) were marred by age-group imprecision that of Forgacs (1957) lacked a norm group and in the case of Brookler & Pulec (1970) hypo-reactive pathologies were sampled. The latter five studies therefore appear only weakly contradictory

The age function for adult vestibular behavior which we have described does not portray a simple parallel to hearing. High frequency hearing loss proceeds rather directly with age yielding a strong linear correlation. Such is easily interpreted in terms of gradual tissue aging and cell death (presbycusis) and "wear and tear" (sociocusis, Glorig & Nixon 1962) Vestibular age decrement in the adult describes a response process which at first appears irritative before becoming depressed. Two highly speculative explanations for this process will be offered below (1) Inhibitory Release, and (2) Local Vascular Influences

Inhibitory release

Several CNS "centers" have been clearly implicated in the inhibitory modulation of vestibular responses (Gernandt, 1967) McCabe (1965) has proposed that the limits of the slow phase sweep of nystagmus are regulated by inhibitory neurons in the reticular formation. A relaxation of the latter would permit increased amplitudes and MES. Chladek (1966) noticed hyper reactivity upon testing subjects over 60 years old and commented "The finding of an increased reaction to vestibular stimulation in old age is often without doubt, in connection with the decreased inhibitory activity of the central vestibular neurons" (p 15)

A hyper reactive caloric response is often said to indicate a pathological failure (release) of an inhibitory mechanism within the vestibular system particularly its central portions (Torok & Derbyshire, 1968) In this connection the observed influence of age on caloric nystagmus mimics the effect traceable to a central lesion This is a frequent state of affairs regarding aging and pathology that sometimes renders their effects indistinguishable if indeed a pure and separable effect of age, *per se* exists. Alluding to an "age effect" here is merely a convenient way to summarize measurable changes which correlate with chronological age. Some theorists find it useful to view post maturational aging as a gradual process of diffuse brain damage.

A well known theory on the behavioral effects of aging holds that aging is normally accompanied by a reduction in neural excitability one manifestation of which is a loss of central inhibitory control (Birren, 1959) This hypothesis was derived from behavioral data indicating that older persons show a reduced capacity to withhold responses in laboratory performance tasks. Obviously such behaviors involve high levels of cognitive function while caloric nystagmus is simply reflexive. This ready application to diverse aging phenomena marks the appeal of the central inhibitory loss notion. A testable hypothesis therefrom is that middle-aged subjects should be less able to exert voluntary control over induced nystagmus than young adults. A related hypothesis is based on the phenomenon of suppression (Barber &

Zusammenfassung

293 untersuchte, schwindelanfällige Patienten im Alter zwischen 20 und 88 Jahren wurden der kalorischen-Nystagmus- und Békésy-Gehör Prüfung unterworfen. Bis in das 7. Lebensjahrzehnt konnte eine Reaktionszunahme mit dem Alter festgestellt werden, danach eine Abnahme. Dies konnte am besten an hand der Frequenz und der langsamen Nystagmuskomponente, weniger ausgeprägt an hand der Amplitude, der Latenz, der Dauer und der schnellen Nystagmuskomponente gezeigt werden. Altersabhängige Nystagmuszunahme war ausgeprägter im warmen Bereich als im kalten. Das Vorkommen von spontanem und statischem Nystagmus war nicht altersbedingt. Hörvermögen und kalorischer Nystagmus wiesen keine gegenseitige Abhängigkeit auf wenn gleiche Altersgruppen miteinander verglichen wurden, mit einer Ausnahme: Männliche Patienten mit starkem Gehörverlust im hohen Frequenzbereich wiesen einen stärkeren Nystagmus auf als jene ohne Gehörverlust, ganz gleich welchen Alters, wobei man an einen häufig an Cochlea und Vestibularapparat auftretenden Degenerationsprozess denken kann. Eine spekulative Erklärung der beobachteten Alterserscheinungen wurde auf der Basis vaskulärer Einflüsse und Verlust zentraler Inhibition geboten.

Résumé

Des examens d'ouïe — ceux de Békésy et ceux basés sur le nystagmo calorique — furent effectués avec 293 patients sélectionnés, souffrant de vertige (étourdissement) et dont l'âge variait entre 20 ans et 88 ans. Tous les paramètres de nystagme manifestaient une reactivité croissante au fur et à mesure que l'âge avançait dans la septième décade après quoi un déclin s'accentuait. La meilleure façon de le démontrer était par fréquence et vélocité de phase lente une démonstration moins accusée s'obtient par amplitude latence durée, et vélocité de phase rapide

Des augmentations de l'âge dans le nystagme etaient plus prononcées pour les stimulus chauds qu'elles ne l'étaient pour les stimulus froids. Le taux des nystagmes spontanés ou positionnels ne variait point avec l'âge des patients.

L'acuité auditive et le nystagme calorique n'accusaient aucune corrélation lorsqu'un âge uniforme fut considéré. Toutefois il y eut une seule exception à savoir Les mâles avec des pertes d'ouïe à haute fréquence manifestaient un nystagme plus fort que les individus sans perte, indépendamment de l'âge. Cette circonstance suggère donc un processus diminué que le limaçon et l'appareil vestibulaire ont en commun.

Une explication spéculative des effets observés quant à l'âge fut formulée par nous, s'appuyant sur des influences vasculaires, ainsi que sur la *perte d'inhibition centrale*.

more severely occluded labyrinthine vessels, as would be expected in very old subjects the vasodilatory augmentation by warm calorics would become less and less effective. An additional factor in the very old subject is that the progressive depression of neural excitability will have become quite advanced and vestibular hypo-reactivity will come to the fore.

For the cold stimulus the vasoconstrictive action produces an opposite effect. It tends to reduce the resting discharge of the irrigated side allowing the discharge of the contralateral side to predominate. As is well known this produces nystagmus which beats away from the cold irrigated side In the young subject, the cold stimulus constricts his patent blood vessels effectively and he may respond with even longer durations and shorter latencies to cold water than he does to warm. On the already partially constricted vessels of middle aged subjects however we assume that the cold water produces little further constriction. One might expect the subsequent caloric response to be quite weak in middle-aged subjects, but a moderate nystagmus is still induced due to the relaxation of inhibitory control Apparently inhibitory release compensates for the deficient vasoconstrictive action so that middle aged subjects show about the same response strength to cold stimulation as the young.

In the foregoing, which admittedly is largely conjectural two augmenting mechanisms have been proposed as bases for the intensified nystagmus following warm irrigations in middle-aged subjects namely vasodilation of narrowed vessels and central inhibitory release. For cold irrigations inhibitory release alone facilitates nystagmus in middle-aged subjects despite a compromised vascular influence. The augmenting mechanisms appear to override, for two or three decades, an opposing force which likewise develops with age depressed neural excitability The latter is proposed to become more prominent in older age (> 70) as manifested by caloric hypo-reactivity

A quotation from Pavlov is most pertinent to the present conception the inhibitory process first and foremost and then the liveliness of the nerve processes, suffer from the development of senile changes." (Gakkel & Zinina 1953)

VI Summary

Caloric nystagmus and Békésy hearing tests were administered to 293 screened dizziness patients ranging in age from 20 to 88 All nystagmus parameters revealed increased responsivity with age into the 60 s followed by a decline. This was shown best by frequency and slow phase velocity and to a lesser extent by amplitude latency duration and fast phase velocity Age increments in nystagmus were more pronounced for warm stimuli than cold. The incidence of spontaneous or positional nystagmus did not vary with age. Hearing acuity and caloric nystagmus showed no intercorrelations when age was held constant with one exception Males with high frequency hearing losses manifested stronger nystagmus than subjects without loss regardless of age suggesting a decremental process common to the cochlea and vestibular apparatus. A speculative explanation of the observed age effects was offered based on vascular influences and loss of central inhibition.

CONTENTS

Introduction

n differentiating between cochlear and retrocochlear hearing impairment, the importance of a test for loudness recruitment was demonstrated by Dix, Hallpike & Hood in 1948 and verified by Eby & Williams in 1951 Three later tests—Békésy (Jerger 1960 a· Owens, 1964) Short Increment Sensitivity Index (Jerger et al 1959 Yantis & Decker 1964 Owens, 1965) and Tone Decay (Carhart, 1957 Sorensen, 1962 Owens, 1964 Hopkinson & Thomas, 1967) have also proved to be of value in such differentiation.

Some reports have indicated however that results from all of these special tests can, on occasion, be misleading. Brand & Rosenberg (1963) Johnson & House (1964) and Shapiro & Naunton (1967) have reported patients with cochlear audiologic signs who, in fact, had a retrocochlear neoplasm. Conversely Jerger et al. (1961) ha e reported that some patients with a sudden hearing loss will show audiologic signs indicating a retrocochlear lesion although neurologic studies are negative with respect to neoplasm.

It thus seemed worthwhile to attempt an evaluation of the contribution of audiology to localization of a lesion affecting the auditory system. The importance of a total work-up involving several disciplines has been documented in recent monographs and articles by Busis (1965) Eichel, Hedgecock & Williams (1966) House (1968) Parker Decker & Richards (1968) Stroud & Thalmann (1969) and in the Third Workship Proceedings (1969 a 1969 b) The special concern regarding the audiologic contribution stems from the well-known facts that hearing loss is often the patient s first complaint—with lesions involving the VIIIth nerve, for example—and that early detection is important. (Olivecrona, 1967 House, 1968)

The aims of the present survey were· (1) to assess the role of pure-tone findings and speech discrimination scores in localization of lesion (2) to report the accuracy of four special tests in localization of lesion, (3) to determine whether certain constellations of test results can help predict a particular kind or location of lesion and (4) to explore trends that may indicate directions for more definitive studies.

Subjects

Patients with sensorineural hearing loss, who had been referred for special audiologic testing to help n localization of lesion, were divided into groups as shown in Table 1 *Menière s Disease* (N 147) *Other Cochlear Lesion* (N-77) *Retroc chlear Lesion* (N-88) and *Sudden L s* (N 100)

Menière disease

The subjects in this group all had the symptom-triad of hearing loss, tinnitus, and episodic spinning" vertigo that defines Menière s disease, and the three symptoms were clearly interrelated. This triad of symptoms has been associated consistently with a hydrops of the labyrinth (Hallpike & Cairns, 1938 Lindsay 1942 Schuknecht, 1963 Altmann & Kornfeld, 1965 Lindsay Kohut & Scarra, 1967). All patients were diagnosed by otolaryngologists on the staff at the University of California, San Francisco, who were highly alert to the possibility of retrocochlear involvement. X-ray

Introduction

differentiating between cochlear and retrocochlear hearing impairment, the importance of test for loudness recruitment was demonstrated by Dix, Hallpike & Hood in 1948 and verified by Eby & Williams in 1951 Three later tests—Békésy (Jerger 1960 a Owens, 1964), Short Increment Sensitivity Index (Jerger et al., 1959 Yantis & Decker 1964 Owens, 1965) and Tone Decay (Carhart, 1957 Sorensen, 1962 Owens, 1964 Hopkinson & Thomas, 1967) have also proved to be of value in such differentiation.

Some reports have indicated, however that results from all of these special tests can, on occasion, be misleading. Brand & Rosenberg (1963) Johnson & House (1964), and Shapiro & Naunton (1967) have reported patients with cochlear audiologic signs who, *in fact*, had a retrocochlear neoplasm. Conversely Jerger et al (1961) have reported that some patients with a sudden hearing loss will show audiologic signs indicating a retrocochlear lesion although neurologic studies are negative with respect to neoplasm.

It thus seemed worthwhile to attempt an evaluation of the contribution of audiology to localization of a lesion affecting the auditory system. The importance of a total work-up involving several disciplines has been documented in recent monographs and articles by Buis (1965) Eichel, Hedgecock & Williams (1966) House (1968) Parker Decker & Richards (1968) Stroud & Thalmann (1969) and in the Third Workshop Proceedings (1969 *a* 1969 *b*). The special concern regarding the audiologic contribution stems from the well-known facts that hearing loss is often the patient's first complaint—with lesions involving the VIIIth nerve, for example—and that early detection is important. (Olivecrona, 1967 House, 1968).

The aims of the present survey were: (1) to assess the role of pure-tone findings and speech discrimination scores in localization of lesion (2) to report the accuracy of four special tests in localization of lesion (3) to determine whether certain constellations of test results can help predict a particular kind or location of lesion and (4) to explore trends that may indicate directions for more definitive studies.

Subjects

Patients with sensorineural hearing loss, who had been referred for special audiologic testing to help in localization of lesion, were divided into groups as shown in Table 1 *Menere's Disease* (N 147) *Other Cochlear Lesion* (N-77) *Retrocochlear Lesion* (N-88) and *Sudden L* (N 100)

Meniere disease

The subjects in this group all had the symptom-triad of hearing loss, tinnitus, and episodic spinning vertigo that defines Menière's disease, and the three symptoms were clearly interrelated. This triad of symptoms has been associated consistently with a hydrops of the labyrinth (Hallpike & Cairns, 1938 Lindsay 194 Schuknecht, 1963 Altmann & Kornfeld, 1965 Lindsay Kohut & Sciarra, 1967) All patients were diagnosed by otolaryngologists on the staff at the University of California, San Francisco, who were highly alert to the possibility of retrocochlear involvement. X-ray

(*c*) cysts, (*d*) brain-stem gliomas, and (*e*) other Sheath tumors included those labeled neuroma, neurinoma, perineural fibroblastoma, neurilemmoma, schwannoma, and acoustic (VIIIth nerve) tumor. Among the cysts were *epidermoid*, *arachnoid*, and those referred as "type unknown." The brain-stem glioma classification included astrocytomas. Diagnoses are listed in Table 2. Insofar as could be determined from operative reports, the neoplasm was ipsilateral to the hearing impairment in all instances.

Sudden loss

All of these patients had had dramatic onset of hearing loss, usually severe. Descriptions of the onset were vivid and detailed, in contrast to those given by the other patients in the survey. Tinnitus, vestibular symptoms, or both had sometimes occurred simultaneously with the hearing loss. While the tinnitus, if occurring, tended to persist, the vestibular symptoms, although sometimes lasting for several days, typically failed to recur after subsiding. In short, the onset of sudden loss, with or without tinnitus and vestibular symptoms, was related to a single episode. Obscure etiology is inherent in the definition of sudden loss employed here. Loss of hearing due to head injury or mumps, for example (see Welsh & Welsh, 1963), is not included in the definition.

All patients in the *Sudden Loss* group were examined and diagnosed by staff otolaryngologists. Neurologic consultation and X-rays of the internal auditory meati and petrous pyramids (all normal) were obtained for most of these patients and several in the group were referred for complete medical and neurologic studies to rule out retrocochlear involvement. The literature suggests, however, that retrocochlear lesion in the form of a neoplasm is rarely found in hearing loss of sudden onset as defined above. Sheehy (1960) reported three patients with retrocochlear lesion in a series of 247 patients with sudden loss. Hallberg (1956) reported two in a series of 178 patients. None were found among our *Sudden Loss* patients. Of our 88 *Retrocochlear Lesion* patients, only one, a patient with a meningioma, reported a sudden onset of hearing loss. She described her loss as beginning with a "pop." However, she presented with other non-auditory symptoms of retrocochlear involvement.

Procedure

The audiologic records for all of these groups were obtained over a period of approximately 6 years. The tests were done when the patients were referred to us and then, at a later date, their records were checked for the final diagnosis. Although the patients forming the *Retrocochlear Lesion group* were unselected, a number of patients with Menière's disease and some who had experienced sudden loss were omitted because they had not been given the special tests. The special requirements already outlined for the *Other Cochlear Lesion* group served to exclude as many as 50 patients, most of whom had symptoms suggesting hydrops. Thus, the sampling, although believed to be unbiased, was not truly random; neither did it represent a critical incidence. At several points throughout the survey, analyses were undertaken on pertinent questions. The Ns for these analyses differed according to the number of patients on whom data were available at the time.

The audiologic evaluations were done in one clinic by audiologists employing essentially the same test methods. In the majority of cases the writer either did the evaluation or participated as an observer.

studies of the internal auditory meati (all normal) were obtained for 76 of the patients. Neurologic consultation was arranged for all patients when there was suspicion of retrocochlear lesion.

In two patients, the presence of the hearing loss-tinnitus-vertigo triad was deceptive. One patient was eventually found to have a cyst in the cerebellopontine angle and the other a glomus tumor invading the labyrinth. The first patient was included in the *Retrocochlear Lesion* group the second was excluded from the survey because involvement of the VIIIth nerve, although strongly suspected, could not be verified Golding Wood (1960) described a patient whose symptoms simulated Menière s disease despite the presence of an acoustic neurinoma but stressed the infrequency of such a case

Other cochlear lesion

In these patients, vestibular symptoms differed from the episodic, spinning vertigo of Menière s disease or were absent About one-third of the group had symptoms and signs suggesting hydrops often heard complaints, for example were roaring" tinnitus, fluctuating hearing loss, sensitivity to loud sounds, and a feeling of fullness. The most common diagnoses were atypical Menière s disease" and labyrinthine hydrops" The remaining two-thirds of the group had hearing losses thought to be associated with such factors as vascular disorders lues, allergy and diabetes. Most often the diagnosis was end-organ lesion, etiology unknown Patients with hearing loss primarily related to prolonged noise exposure ototoxic drugs or old age were excluded

All patients in the *Other Cochlear Lesion* group had X ray studies of the internal auditory meati and petrous pyramids, including tomograms in many instances. Over half of this group had also been examined by a neurologist. All neurologic studies and examinations were normal According to published observations (Crabtree & House, 1964 Valvassori 1969)

Table 1 *Patients who had been referred for special audiologic testing in localization of lesion*

retrocochlear lesions are sometimes missed by radiography in the absence of iophendylate studies. Such studies were obtained on only a few patients in our group It can only be said that patients were excluded from the *Other Cochlear Lesion* group at the slightest suspicion of retrocochlear lesion expressed by the otolaryngologists, neurologists and neurosurgeons involved.

Retrocochlear lesion

Eighty three of the 88 patients in the *Retrocochlear Lesion* group had surgically identified neoplasms, four had multiple sclerosis, and one had an internal carotid aneurysm shown by vertebral arteriograms to be pressing against the VIIIth nerve in much the same manner as a tumor Classification of neoplasms was difficult because of different terminology used by individual neurologists, neurosurgeons, otolaryngologists, and histopathologists, but the following classifications seemed appropriate for this survey (*a*) sheath tumors, (*b*) meningiomas,

Table 2. *Diagnoses for the* Retrocochlear Lesion *group*

Among the cysts were epidermoid, arachnoid, and those referred as "type unknown." The brain-stem glioma classification included astrocytomas. Diagnoses are listed in Table 2. Insofar as could be determined from operative reports, the neoplasm was ipsilateral to the hearing impairment in all instances.

Sudden loss

All of these patients had had dramatic onset of hearing loss, usually severe. Descriptions of the onset were vivid and detailed, in contrast to those given by the other patients in the survey. Tinnitus, vestibular symptoms, or both had sometimes occurred simultaneously with the hearing loss. While the tinnitus, if occurring, tended to persist, the vestibular symptoms, although sometimes lasting for several days, typically failed to recur after subsiding. In short, the onset of sudden loss, with or without tinnitus and vestibular symptoms, was related to a single episode. Obscure etiology is inherent in the definition of sudden loss employed here. Loss of hearing due to head injury or mumps, for example (see Welsh & Welsh, 1963), is not included in the definition.

All patients in the *Sudden Loss* group were examined and diagnosed by staff otolaryngologists. Neurologic consultation and X-rays of the internal auditory meati and petrous pyramids (all normal) were obtained for most of these patients and several in the group were referred for complete medical and neurologic studies to rule out retrocochlear involvement. The literature suggests, however, that retrocochlear lesion in the form of a neoplasm is rarely found in hearing loss of sudden onset as defined above. Sheehy (1960) reported three patients with retrocochlear lesion in a series of 247 patients with sudden loss. Hallberg (1956) reported two in a series of 178 patients. None were found among our *Sudden Loss* patients. Of our 88 *Retrocochlear Lesion* patients, only one, a patient with a meningioma, reported a sudden onset of hearing loss. She described her loss as beginning with a "pop." However she presented with other non-auditory symptoms of retrocochlear involvement.

Procedure

The audiologic records for all of these groups were obtained over a period of approximately 6 years. The tests were done when the patients were referred to us and then, at a later date, their records were checked for the final diagnoses. Although the patients forming the *Retrocochlear Lesion* group were unselected, a number of patients with Menière's disease and some who had experienced sudden loss were omitted because they had not been given the special tests. The special requirements already outlined for the *Other Cochlear Lesion* group served to exclude as many as 50 patients, most of whom had symptoms suggesting hydrops. Thus, the sampling, although believed to be unbiased, was not truly random; neither did it represent a critical incidence. At several points throughout the survey, analyses were undertaken on pertinent questions. The Ns for these analyses differed according to the number of patients on whom data were available at the time.

The audiologic evaluations were done in one clinic by audiologists employing essentially the same test methods. In the majority of cases the writer either did the evaluation or participated as an observer.

Pure-Tone Findings

Bilateral pure-tone loss

The first consideration regarding pure-tone findings was the occurrence of bilateral pure tone loss (see Table 3) defined arbitrarily by threshold levels of greater than 25 dB in both ears at four or more of the six octave interval frequencies within the 250–8 000 Hz range

In the *Menière s Disease* group bilateral loss occurred in 26 of the 147 patients Their histories suggested that, in seven of the 26 both ears were affected at about the same time in nine the second ear was affected at a later date and in the remaining 10 the information regarding onset was unreliable In two of the last 10 it seemed likely that the impairment in the poorer ear was superimposed on a bilateral presbycusis Actually then 24 (16%) patients in the *Menière s Disease* group had bilateral loss stemming from a presumed hydrops.

Of the 77 patients in the *Other Cochlear Lesion* group 15 showed bilateral loss but in only nine (12%) were both ears seemingly affected by the same kind of impairment The onset was at about the same time for both ears in seven of the nine, while in the other two the history of onset was vague In the remaining six of the 15 with bilateral loss, hearing in one ear was noticeably poorer than in the other and the impairment in the poorer ear seemed to have been superimposed on a previous bilateral impairment of a different kind—from presbycusis in three and from long time noise exposure in three

Of the 88 patients in the *Retrocochlear Lesion* group four showed bilateral pure tone impairment. In only one, a patient with von Recklinghausen s disease, did the loss in both ears stem from the same kind of impairment. In the remaining three hearing in one ear was noticeably poorer than in the other and the impairment in the poorer ear seemed to have been superimposed upon a previous bilateral impairment—from presbycusis in two and from noise exposure in one.

In the *Sudden Loss* group bilateral involvement was present in 18 of the 100 patients. In four of the 18 both ears seemingly were affected at the same time in two of these four the onset seemed associated with a major operation In the remaining 14 of the 18 patients the history revealed that at the time of sudden onset in one ear a long-standing loss had been present in the other ear In these 14 patients the opposite-ear loss reportedly had not been of sudden onset and its etiology was indeterminable

It should be stressed that we are talking here only of threshold impairment in four of the *Retrocochlear Lesion* patients to be discussed later bilateral impairment that had not been reflected by pure tone threshold elevations could be demonstrated by tone decay and Bekesy tracings Also we are excluding patients in whom a tumor extended to the opposite side at a late stage

Bilateral pure-tone loss from the same impairment was thus uncommon in all groups. It was highest in the *Menière s Disease* and *Other Cochlear Lesion* groups (16% and 12% respectively) relatively less common in the *Sudden Loss group* (4%) and uncommon in the *Retrocochlear Lesion* group (1 2%) Thus if von Recklinghausen s disease is excluded from consideration retrocochlear lesion would rarely be expected with bilateral pure-tone loss.

The literature presents the same general trends for bilateral loss in patients with Menière s disease sudden loss, and retrocochlear involvement although widely varying percentages have been given probably in part because of differences in definition For patients with Menière s disease, bilateral loss was reported by Hallberg (1956) in 19 of 56 patients (34%) and by Goldingwood (1960) in 94 of 214 patients (44%) In contrast Day (1963) reported bilateral involvement in only 5 to

10 % of Menière's disease patients, with the two ears usually becoming involved simultaneously. Delayed involvement (after 6 months) in the second ear occurred in less than 2% of his more than 1 500 cases" Schuknecht (1963) reported that about 10% of patients with Menière's disease had bilateral loss.

Regarding retrocochlear impairment, Nager (1969) stated that "Bilateral eighth nerve tumors occur in about 4% of all acoustic neurinomas. In most instances they are associated with von Recklinghausen's disease." Hitselberger & Hughes (1968) recently reported bilateral involvement in 12 of 212 patients with VIIIth nerve tumor. Without mentioning von Recklinghausen's disease, they attributed these tumors to "an abortive form of neurofibromatosis". Caparosa (1966) presented three patients with bilateral VIIIth-nerve involvement, all three of whom had von Recklinghausen's disease. On the other hand, von Recklinghausen's disease was evident in only one of the two patients with bilateral acoustic tumors recently reported by DeMoura et al. (1969).

Although bilateral hearing losses have been reported with brain-stem lesions, in contrast to the above VIIIth-nerve lesions, such data are sparse. Bilateral reduction in hearing sensitivity was described by Horrax & Bailey (1925) in five of 12 patients with pineal body tumors (pinealoma); several years later, however, Nylen (1939) concluded that hearing reduction was not a common finding with pinealoma, and that it was a late symptom when it did appear. In other kinds of brain-stem lesion Nylen reported very low percentages of bilateral hearing loss.

With respect to sudden loss, Hallberg (1956) found only two patients with bilateral involvement in a series of 89 patients, while Schuknecht et al. (196-) stated that both ears were involved in less than 70 of such patients.

Total unilateral loss

Total unilateral loss was defined by an inability to hear pure tones in the affected ear at the audiometer limits (90 dB at 250 and 8 000 Hz, and 110 dB at the intervening octave-interval frequencies re audiometric zero). Included in this definition are patients who responded near audiometer limits for the frequencies 250 and 500 Hz, but who were not sure whether they heard an actual tone or simply *felt* the signals generated in the earphone.

As shown in Table 3, total unilateral hearing loss was found in one of the *Menière's Disease* group, in none of the *Other Cochlear Lesion* group, in six of the *Retrocochlear Lesion* group (7%), and in nine of the *Sudden Loss* group (9%).[1]

Goodman (1965), employing the same definition of total loss, found only one patient with total unilateral loss in his group of 43 patients with Menière's disease and pointed up the rarity of such loss by describing this patient at length. Hallberg (1956) reported five patients with total unilateral loss in a series of 56 patients with Menière's disease. He also reported that, in a series 89 patients with sudden unilateral loss, the deafness was total in 36%. In neither his Menière's disease group nor his sudden loss group was a definition of total unilateral loss given. Brand & Rosenberg (1963) reported 10 cases of total unilateral loss in a selected series of 22 patients with VIIIth-nerve tumor, and Johnson (1965) reported 20 in a series of 110 such patients (18%). Buey & Isamat (1961) stated that acoustic neurinoma "... is characterized by progressive deafness which soon reaches the point where all useful hearing is lost"

According to evidence from the literature and from the present series, then, total unilateral loss is found primarily in patients experiencing sudden loss or loss associated with VIIIth-nerve tumor. It seems unlikely that our nine *Sudden Loss* patients with complete unilateral loss had an VIIIth-nerve tumor. In one, hearing returned almost completely and in

---

[1] It should be mentioned that four Menière's Disease patients with bilateral loss demonstrated a total loss in the poorer ear, which had been affected several years before the better ear.

1 t

Pure-Tone Findings

Bilateral pure-tone loss

The first consideration regarding pure-tone findings was the occurrence of bilateral pure tone loss (see Table 3) defined arbitrarily by threshold levels of greater than 25 dB in both ears at four or more of the six octave-interval frequencies within the 250–8 000 Hz range.

In the *Menière s Disease* group bilateral loss occurred in 26 of the 147 patients Their histories suggested that in seven of the 26 both ears were affected at about the same time in nine, the second ear was affected at a later date, and in the remaining 10 the information regarding onset was unreliable. In two of the last 10 it seemed likely that the impairment in the poorer ear was superimposed on a bilateral presbycusis. Actually then, 24 (16%) patients in the *Menière s Disease* group had bilateral loss stemming from a presumed hydrops.

Of the 77 patients in the *Other Cochlear Lesion* group 15 showed bilateral loss but in only nine (12%) were both ears seemingly affected by the same kind of impairment. The onset was at about the same time for both ears in seven of the nine, while in the other two the history of onset was vague In the remaining six of the 15 with bilateral loss hearing in one ear was noticeably poorer than in the other and the impairment in the poorer ear seemed to have been superimposed on a previous bilateral impairment of a different kind—from presbycusis in three and from long-time noise exposure in three

Of the 88 patients in the *Retrocochlear Lesion* group four showed bilateral pure tone impairment. In only one a patient with von Recklinghausen s disease did the loss in both ears stem from the same kind of impairment. In the remaining three, hearing in one ear was noticeably poorer than in the other and the impairment in the poorer ear seemed to have been superimposed upon a previous bilateral impairment—from presbycusis in two, and from noise exposure in one.

In the *Sudden Loss* group, bilateral involvement was present in 18 of the 100 patients. In four of the 18 both ears seemingly were affected at the same time in two of these four the onset seemed associated with a major operation In the remaining 14 of the 18 patients the history revealed that at the time of sudden onset in one ear a long-standing loss had been present in the other ear In these 14 patients the opposite-ear loss reportedly had not been of sudden onset and its etiology was indeterminable.

It should be stressed that we are talking here only of threshold impairment In four of the *Retrocochlear Lesion* patients to be discussed later bilateral impairment that had not been reflected by pure-tone threshold elevations could be demonstrated by tone decay and Bekesy tracings Also, we are excluding patients in whom a tumor extended to the opposite side at a late stage

Bilateral pure tone loss from the same impairment was thus uncommon in all groups. It was highest in the *Menière s Disease* and *Other Cochlear Lesion* groups (16% and 12% respectively) relatively less common in the *Sudden Loss group* (4%) and uncommon in the *Retrocochlear Lesion* group (1 2%) Thus if von Recklinghausen s disease is excluded from consideration retrocochlear lesion would rarely be expected with bilateral pure-tone loss.

The literature presents the same general trends for bilateral loss in patients with Menière s disease, sudden loss, and retrocochlear involvement, although widely varying percentages have been given probably in part because of differences in definition For patients with Menière s disease bilateral loss was reported by Hallberg (1956) in 19 of 56 patients (34%) and by Goldingwood (1960) in 94 of 214 patients (44%) In contrast, Day (1963) reported bilateral involvement in only 5 to

10% of Menière's disease patients, with the two ears usually becoming involved simultaneously. Delayed involvement (after 6 months) in the second ear occurred in less than 2% of his more than 1 500 cases." Schuknecht (1963) reported that about 10% of patients with Menière's disease had bilateral loss.

Regarding retrocochlear impairment, Nager (1969) stated that "Bilateral eighth nerve tumors occur in about 4% of all acoustic neurinomas. In most instances they are associated with von Recklinghausen's disease ... " Hitselberger & Hughes (1968) recently reported bilateral involvement in 12 of 212 patients with VIIIth-nerve tumor. Without mentioning von Recklinghausen's disease, they attributed these tumors to "an abortive form of neurofibromatosis." Caparosa (1966) presented three patients with bilateral VIIIth-nerve involvement, all three of whom had von Recklinghausen's disease. On the other hand, von Recklinghausen's disease was evident in only one of the two patients with bilateral acoustic tumors recently reported by DeMoura et al. (1969).

Although bilateral hearing losses have been reported with brain-stem lesions, in contrast to the above VIIIth-nerve lesions, such data are sparse. Bilateral reduction in hearing sensitivity was described by Horrax & Bailey (1925) in five of 12 patients with pineal body tumors (pinealoma); several years later, however, Nylén (1939) concluded that hearing reduction was not a common finding with pinealoma, and that it was a late symptom when it did appear. In other kinds of brain-stem lesion Nylén reported very low percentages of bilateral hearing loss.

With respect to sudden loss, Hallberg (1956) found only two patients with bilateral involvement in a series of 89 patients, while Schuknecht et al. (1962) stated that both ears were involved in less than 20% of such patients.

Total unilateral loss

Total unilateral loss was defined by an inability to hear pure tones in the affected ear at the audiometer limits (90 dB at 250 and 8 000 Hz, and 110 dB at the intervening octave-interval frequencies re audiometric zero). Included in this definition are patients who responded near audiometer limits for the frequencies 250 and 500 Hz, but who were not sure whether they *heard* an actual tone or simply *felt* the signals generated in the earphone.

As shown in Table 3, total unilateral hearing loss was found in one of the *Menière's Disease* group, in none of the *Other Cochlear Lesion* group, in six of the *Retrocochlear Lesion* group (7%), and in nine of the *Sudden Loss* group (9%).[1]

Goodman (1965), employing the same definition of total loss, found only one patient with total unilateral loss in his group of 43 patients with Menière's disease and pointed up the rarity of such loss by describing this patient at length. Hallberg (1956) reported five patients with total unilateral loss in a series of 56 patients with Menière's disease. He also reported that, in a series 89 patients with sudden unilateral loss, the deafness was total in 36%. In neither his Menière's disease group nor his sudden loss group was a definition of total unilateral loss given. Brand & Rosenberg (1963) reported 10 cases of total unilateral loss in a selected series of 22 patients with VIIIth-nerve tumor, and Johnson (1965) reported 20 in a series of 110 such patients (18%). Bucy & Ismat (1961) stated that acoustic neurinoma "... is characterized by progressive deafness which soon reaches the point where all useful hearing is lost."

According to evidence from the literature and from the present series, then, total unilateral loss is found primarily in patients experiencing sudden loss or loss associated with VIIIth-nerve tumor. It seems unlikely that our nine *Sudden Loss* patients with complete unilateral loss had an VIIIth-nerve tumor. In one, hearing returned almost completely and in

[1] It should be mentioned that four Menière's Disease patients with bilateral loss demonstrated a total loss in the poorer ear, which had been affected several years before the better ear.

1 Tiress

Pure-Tone Findings

Bilateral pure-tone loss

The first consideration regarding pure-tone findings was the occurrence of bilateral pure tone loss (see Table 3) defined arbitrarily by *threshold* levels of greater than 25 dB in both ears at four or more of the six octave interval frequencies within the 250–8 000 Hz range.

In the *Menière s Disease* group bilateral loss occurred in 26 of the 147 patients Their histories suggested that, in seven of the 26 both ears were affected at about the same time in nine the second ear was affected at a later date and in the remaining 10 the information regarding onset was unreliable In two of the last 10 it seemed likely that the impairment in the poorer ear was superimposed on a bilateral presbycusis Actually then, 24 (16%) patients in the *Menière s Disease* group had bilateral loss stemming from a presumed hydrops.

Of the 77 patients in the *Other Cochlear Lesion* group 15 showed bilateral loss but in only nine (12%) were both ears seemingly affected by the same kind of impairment. The onset was at about the same time for both ears in seven of the nine, while in the other two the history of onset was vague In the remaining six of the 15 with bilateral loss, hearing in one ear was noticeably poorer than in the other and the impairment in the poorer ear seemed to have been superimposed on a previous bilateral impairment of a different kind—from presbycusis in three and from long time noise exposure in three

Of the 88 patients in the *Retrocochlear Lesion* group four showed bilateral pure tone impairment. In only one, a patient with von Recklinghausen s disease, did the loss in both ears stem from the same kind of impairment. In the remaining three, hearing in one ear was noticeably poorer than in the other and the impairment in the poorer ear seemed to have been superimposed upon a previous bilateral impairment—from presbycusis in two, and from noise exposure in one.

In the *Sudden Loss* group, bilateral involvement was present in 18 of the 100 patients. In four of the 18 both ears seemingly were affected at the same time in two of these four the onset seemed associated with a *major* operation In the remaining 14 of the 18 patients, the history revealed that at the time of sudden onset in one ear a long-standing loss had been present in the other ear In these 14 patients, the opposite-ear loss reportedly had not been of sudden onset, and its etiology was indeterminable.

It should be stressed that we are talking here only of threshold impairment in four of the *Retrocochlear Lesion* patients, to be discussed later bilateral impairment that had not been reflected by pure tone threshold elevations could be demonstrated by tone decay and Bekesy tracings. Also we are excluding patients in whom a tumor extended to the opposite side at a late stage

Bilateral pure-tone loss from the same impairment was thus uncommon in all groups. It was highest in the *Menière s Disease* and *Other Cochlear Lesion* groups (16% and 12% respectively) relatively less common in the *Sudden Loss group* (4%) and uncommon in the *Retrocochlear Lesion* group (1 2%) Thus if von Recklinghausen s disease is excluded from consideration, retrocochlear lesion would rarely be expected with bilateral pure-tone loss.

The literature presents the same general trends for bilateral loss in patients with Menière s disease, sudden loss, and retrocochlear involvement, although widely varying percentages have been given, probably in part because of differences in definition For patients with Menière s disease bilateral loss was reported by Hallberg (1956) in 19 of 56 patients (34%) and by Goldingwood (1960) in 94 of 214 patients (44%) In contrast, Day (1963) reported bilateral involvement in only 5 to

Table 5 *Ages of patients with better-ear high-tone loss*

Group	Better ear	Mean age	Number
Menière's Disease	Normal	43	48
	High-tone loss	54	39
Other Cochlear Lesion	Normal	42	26
	High-tone loss	55	22
Retrocochlear Lesion	Normal	35	41
	High-tone loss	58	16
Sudden loss	Normal	41	40
	High-tone loss	59	17

causal relationship. Further he found that in approximately 50 of 100 patients with Menière's disease, a bilateral high-tone loss was present before the onset of hydrops in the affected ear. He felt that in many older persons the hydrops was thus superimposed on an existing loss. Direct evidence in this regard was precluded in the present survey because the patients were seen for the first time only after the loss in the affected ear had occurred. In a sample composed of the first 87 *Menière's Disease* patients, however, the mean age of 39 patients with better-ear high-tone loss was 54 years and the mean age of 48 patients with normal hearing in the better ear was 43 years. The difference of 11 years was significant at the 0.1 level of confidence. Thus, age did appear to play a role in the high-tone loss of the better ear. Considering, then, that hearing loss due to aging is usually bilateral, it does seem likely that high-tone loss was present in the affected ear before the onset of hydrops. The question of causal relationship, however, is beyond the scope of this survey. Ages of other patients who were part of the survey at the same time as the 87 *Menière's Disease* patients were also tallied, and the data are shown in Table 3. In all groups, better-ear high-tone loss seemed associated with older age.

A few of the *Menière's Disease* patients, not included in Table 5, showed a better-ear high-tone loss that seemed entirely due to noise exposure. Because hearing loss from long-time exposure to noise is usually bilateral, although not necessarily the same in each ear, it appears likely that in these patients too high-tone loss existed in the affected ear prior to the onset of hydrops. In any event, because of the prevalence of high-tone loss in the better ear of all groups, it seemed incumbent to include both ears in the classification of pure-tone patterns. The purpose was to permit a more accurate delineation of any presumably superimposed loss in the affected ear.

Accordingly, in cases of better-ear high-tone loss, a pre-existing, bilaterally equal, high-tone loss was assumed and the poorer-ear impairment was viewed as a subsequent superimposition. Looking at both ears, then, five classes of pure-tone patterns emerged for the frequency range of 250 to 8 000 Hz: (1) patterns in which the configurations for the two ears were essentially parallel, (2) patterns in which the two configurations closed or almost closed at the high end of the frequency range, (3) patterns that showed areas or points of constriction between the two configurations, (4) patterns in which a widening occurred between the two configurations in the high-tone range, and (5) patterns in which the two configurations closed or almost closed at both ends of the frequency range, widening in the middle.

Patterns that were highly similar in shape and fairly equal with respect to differences between the ears were sorted out and combined in a representative schematic. A number of such schematics resulted for each group, as shown in Fig. 1 through 5. When the better ear was normal, a straight line 10-dB level was employed as a reference; when the better ear showed a high-tone loss, schematics believed to be representative of the most frequently occurring slopes in each group served as references. In grouping the configurations for the schematics, a special effort was made to portray the actual differences in threshold levels between the two ears.

In defining these patterns, the statistician's "best-fitting straigth line" through the thresholds for each ear from 250 to 8 000 Hz was

Table 3 Bilateral losses and total unilateral losses among the groups studied

Groups	Initial number	Bi lateral loss	Total unilateral loss	Re-maining number
Menière s Disease	147	26	1	120
Other Cochlear Lesion	77	15[a]	0	62
Retrocochlear Lesion	88	4[a]	6	76[b]
Sudden Loss	100	18[a]	9	73

[a] In only 24 *Menière's Disease* patients (16%) nine *Other Cochlear Lesion* patients (12%) one *Retrocochlear Lesion* patient (1.2 %) and four *Sudden Loss* patients (4%) did the loss in each ear seem due to the same kind of impairment.
[b] See text for explanation of the mathematical discrepancy

another it returned partially In two the loss had been present for many years without neurologic signs. In another the loss seemed clearly associated with a virus, and in yet another the loss occurred in an operated ear several weeks after a stapedectomy Of the remaining three, one had had an extensive neurologic work up in which all findings were normal, while in the other two the examining otologist felt confident in ruling out an VIIIth-nerve tumor on the basis of the otologic examination and the circumstances relating to the onset. In any case the evidence suggests that a total unilateral loss in the absence of a history of sudden hearing loss should arouse suspicion of retrocochlear involvement specifically involvement of the VIIIth nerve

Pure-tone patterns

Patients with bilateral loss and patients with total unilateral loss were excluded from the remainder of the survey Those remaining for analysis of pure tone patterns (see Table 3) were as follows.
Menière s Disease (120) *Other Cochlear Lesion* (62) *Retrocochlear Lesion* (76) and *Sudden Loss* (73)

The number remaining in the *Retrocochlear Lesion* group requires explanation. Three of the four patients with bilateral loss (that is, all except the one with von Recklinghausen s disease) were retained because the better-ear impairment was marginal and involved primarily the high tones. As stated previously the better ear impairment in these three patients probably stemmed from exposure to noise (in one) and old age. Five patients were omitted because their pure-tone patterns could not be classified easily according to our system They will be discussed in a later section. If from the initial number of 88 we subtract these five along with the six patients with total unilateral loss and the one patient with von Recklinghausen s disease and bilateral loss, we are left with 76.

The occurrence of high-tone loss in the better ear of a number of patients complicated the classification of pure-tone patterns. High-tone loss was defined by threshold levels no greater than 25 dB for frequencies 250 through 1 000 Hz accompanied by levels greater than 25 dB at 2 000 4 000 and 8 000 Hz, at 4 000 and 8 000 Hz or at 8 000 Hz only A dip at 4 000 Hz was not counted as a high tone loss. Defined in this manner high-tone loss occurred in 55 of the 120 *Menière s Disease* patients (46%) in 31 of the 62 *Other Cochlear Lesion* patients (50%) in 25 of the 76 *Retrocochlear Lesion* patients (33%) and in 26 of the 73 *Sudden Loss* patients (36%) (see Table 4)

Lindsay (1960) thought that high tone loss in the better ear of patients with Menière s disease occurred often enough to suggest a

Table 4 *High-tone loss in the better ear*

Group	Total number	Number with better-ear high-tone loss
Menière s Disease	120	55 (46)
Other Cochlear Lesion	62	31 (50)
Retrocochlear Lesion	76	25 (33)
Sudden Loss	73	6 (36)

Defined by threshold levels no greater than 25 dB for frequencies 250 through 1 000 Hz accompanied by levels greater than 25 dB at 2 000, 4 000, and 8 000 Hz, at 4 000 and 8 000 Hz, or at 8 000 Hz only

Table 5. *Ages of patients with better-ear high-tone loss*

Group	Better ear	Mean age	Number
Menière's Disease	Normal	43	48
	High-tone loss	54	39
Other Cochlear Lesion	Normal	42	26
	High-tone loss	55	22
Retrocochlear Lesion	Normal	35	41
	High-tone loss	58	16

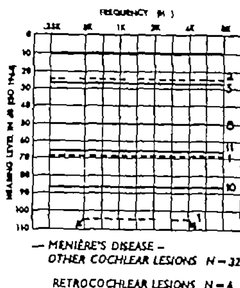
causal relationship Further he found that in approximately 50 of 100 patients with Menière s disease a bilateral high-tone loss was present before the onset of hydrops in the affected ear He felt that in many older persons the hydrops was thus *superimposed* on an existing loss. Direct evidence in this regard was precluded in the present survey because the patients were seen for the first time only after the loss in the affected ear had occurred. In a sample composed of the first 87 *Menière's Disease* patients, however the mean age of 39 patients with better-ear high-tone loss was 54 years and the mean age of 48 patients with normal hearing in the better ear was 43 years The difference of 11 years was significant at the 0 1 level of confidence. Thus, age did appear to play a role in the high-tone loss of the better ear Considering, then, that hearing loss due to aging is usually bilateral, it does seem likely that high-tone loss was present in the affected ear before the onset of hydrops. The question of causal relationship, however is beyond the scope of this survey Ages of other patients who were part of the survey at the same time as the 87 *Menière s Disease* patients were also tallied, and the data are shown in Table 5 In all groups, better-ear high-tone loss seemed associated with older age.



A few of the *Menière s Disease* patients, not included in Table 5 showed a better-ear high-tone loss that seemed entirely due to noise exposure. Because hearing loss *from long-time* exposure to noise is usually *bilateral*, although not necessarily the same in each ear it appears likely that in these patients too high-tone loss existed in the affected ear prior to the onset of hydrops. In any event, because of the prevalence of high-tone loss in the better ear of all groups, it seemed incumbent to include both ears in the classification of pure-tone patterns. The purpose was to permit a *more* accurate delineation of any presumably *superimposed loss in* the affected ear

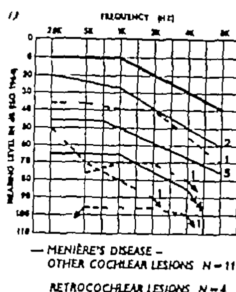
Accordingly in cases of better-ear high-tone loss, a pre-existing, bilaterally equal, high-tone loss was assumed and the poorer-ear impairment was viewed *as a subsequent super* imposition. Looking at both ears, then, five classes of pure-tone patterns emerged for the frequency range of 250 to 8 000 Hz: (1) patterns in which the configurations for the two ears were essentially parallel (2) patterns in which the two configurations closed or almost closed at the high end of the *frequency range* (3) patterns that showed areas or points of constriction between the two configurations (4) patterns in which a widening occurred between the two configurations in the high-tone range; and (5) patterns in which the two configurations closed or almost closed at both ends of the frequency range, widening in the middle.

Patterns that were highly similar in shape and fairly equal with respect to differences between the ears were sorted out and combined in a representative schematic. A number of such schematics resulted *for each group as* shown in Fig. 1 *through 5 When the* better ear was *normal*, a straight line 10-dB level was employed as a reference when the better ear showed a high-tone loss, schematics believed to be representative of the most frequently occurring slopes in each *group* served as references. In grouping the *configurations for the schematics, a special effort* was made to portray *the actual differences in threshold* levels between the two ears.

In defining these patterns, the statistician s best-fitting straight line" through the thresholds for each ear from 250 to 8 000 Hz was

a

b



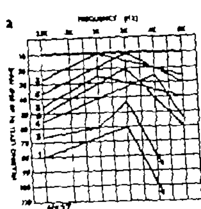


Fig 1 (*a*) A comparison of parallel" patterns for the combined *Menière's Disease + Other Cochlear Lesion* group and for the *Retrocochlear Lesion* group. Normal hearing in the better ear (*b*) A comparison of parallel patterns for the combined *Menière's Disease + Other Cochlear Lesion* group and for the *Retrocochlear Lesion* group. High-tone loss in the better ear

employed two straight edges, one for each ear served in place of actual lines If the two straight edges parted no more than 10 dB at either end of the frequency range relative to the parting at the other end the pattern of configurations was classed as parallel" If the two straight edges parted more than 10 dB at 250 Hz compared to the parting at 8 000 Hz, the pattern of configurations was classed as "closing" When the two edges parted more than 10 dB at 8 000 Hz compared to the parting at 250 Hz, the pattern was classified as widening" The constricting" patterns were typically associated with rising–falling configurations in the affected ear and were easily classified by inspection Similarly the closing both-ends" patterns typically resulted from trough-shaped configurations in the affected ear and were also easily classified by inspection which, as a matter of fact, was true in most cases for all of the patterns.

Arbitrary decisions were required for a few patterns that were difficult to classify For example when no response occurred at 8 000 Hz in the affected ear pattern classification rested on the relation between the two configurations from 250 to 4 000 Hz, unless a response to 8 000 Hz at audiometer limits would have resulted in a widening' classification. When no response occurred at either 8 000 Hz or 4 000 Hz in the affected ear the classification was based on the 250- to 2 000-Hz range unless a response to 4 000 Hz at audiometer limits would have resulted in a widening" classification. When no response occurred in the affected ear at 250 Hz, the classification was based on the pattern of configurations within the 500- to 8 000-Hz range. In cases of a notch at 4 000 Hz in the better ear a pre existing bilateral notch was assumed In three instances of better-ear conductive loss, the bone-conduction hearing levels constituted the configuration for the unaffected ear necessitating the use of only the 250- to 4 000-Hz range.

Finally in five instances where a sharp widening followed a constriction the patterns were classified by inspection according to whether the constricting or the widening aspect prevailed

Table 6 summarizes the patterns for a comparison between groups. We may observe that the parallel" patterns were found in all groups, but in a noticeably smaller proportion of the

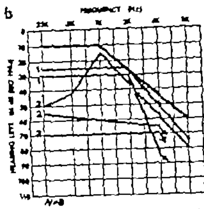

Fig. 2. (*a*) Examples of "constricting" patterns for the *Menière' Disease + Other Cochlear Lesion* combined group. Normal hearing in the better ear. (*b*) Examples of "constricting" patterns for the *Menière's Disease + Other Cochlear Lesion* combined group. High-tone loss in the better ear.

Retrocochlear Lesion group. A comparison of the parallel patterns found among the *Retrocochlear Lesion* group and the combined *Menière's Disease + Other Cochlear Lesion* group is shown in Fig. 1. Particularly of note are three patients in the *Retrocochlear Lesion* group who showed "parallel" patterns accompanied by a minimal difference between the ears on the order of 10–25 dB. In two of the three, hearing in the poorer ear was still within normal range. Of the three patients, two had a sheath tumor and one a brain-stem glioma. This minimal difference with parralled patterns occurred infrequently (five of 182 patients) in the combined *Menière's Disease + Other Cochlear Lesion* group and never in the *Sudden Loss group*. One other *Retrocochlear Lesion* patient showed a minimal-difference "parallel" pattern before developing a high-tone loss in the affected ear, which led to his placement in the "widening" group. This patient was described by Flower & Viehweg in 1961. Similar patterns accompanying retrocochlear involvement have appeared in other studies, but were not stressed by the investigators. For example, Goetzinger & Angell (1965) in presenting a series of audiograms for patients with retrocochlear lesion, included those of two patients in which the ear ipsilateral to a cerebellopontine-angle mass showed thresholds about 70 dB below those of the better ear across the frequency range. In any event, the presence of a minimal-difference parallel pattern should provide an immediate clue to the possibility of retrocochlear involvement.

"Constricting" patterns occurred almost exclusively in the *Menière's Disease* and *Other Cochlear Lesion* groups (see Table 6 and Fig. 2). It thus appears that these patterns may be a unique reflection of hydrops.

"Closing" patterns were predominant in the *Menière's Disease* and *Other Cochlear Lesion* groups (see Table 6 and Fig. 3), particularly in patients with better-ear high-tone loss. These patterns occurred only occasionally in the *Retrocochlear Lesion* group. Consequently, it seems that hydrops might be suspected in the *Other Cochlear Lesion* patients with "closing" patterns. Although these patterns occurred frequently in the *Sudden Loss* group, suspicion of hydrops is probably not justified. For one reason, the "closing" patterns of this group as well as those few that occurred for the *Retrocochlear Lesion* group typically accompanied a greater degree of loss compared to those for the *Menière's Disease* and *Other Cochlear Lesion* patients. For another reason, histopathologic evidence (Perlman & Kimura, 1959; Schuknecht et al., 1962) suggests that hydrops is not commonly found with sudden loss.

The "widening" patterns, although characteristic of the *Retrocochlear Lesion* group, oc

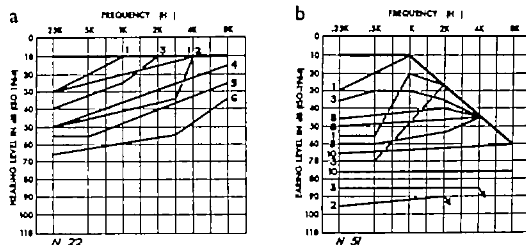

Fig 3 (*a*) Examples of closing patterns, *Menière's Disease + Other Cochlear Lesion* combined group. Normal hearing in the better ear (*b*) Examples of closing patterns, *Menière s Disease + Other Cochlear Lesion* combined group. High-tone loss in the better ear

curred frequently in the *Sudden Loss* group they occurred markedly less often in the *Menière s Disease* and *Other Cochlear Lesion* groups The probability of a widening' pattern in the *Retrocochlear Lesion* group was 0 67 compared with a probability of 0 13 in the combined *Menière s Disease + Other Cochlear Lesion* group In the absence of a history of sudden loss, then, suspicion of retrocochlear involvement should be aroused by a widening" pattern.

Examples of widening" patterns in the *Retrocochlear Lesion* group are shown in Fig. 4 Although the precipitously widening patterns (Fig. 4 *a*) are found frequently in the *Sudden Loss* group as well as in the *Retrocochlear Lesion* group the gradually widening patterns (Fig. 4 *b*) are unusual among the *Sudden Loss* group

In the case of widening" patterns, just as in the case of parallel" patterns, importance should be attached to minimal threshold differences between the ears. Two patients—one with a brain-stem glioma and the other with a chondroma—showed a widening" pattern of this kind (Fig. 4 *b*) which was seldom seen in the other groups. Housa, Gale & Hughes (1968) described five patients who had small

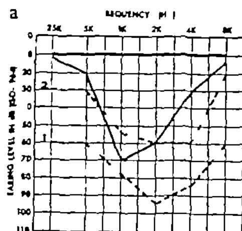
Table 6. *Summary of pure-tone patterns*

Figures in parentheses are percentages

Patterns	Menière's Disease	Other Cochlear	Retro-cochlear	Sudden Loss
Parallel	30 (25.0)	13 (20.9)	8 (11.0)	14 (19.2)
Constricting	25 (20.9)	10 (16.1)	1 (1.0)	1 (1.3)
Closing	52 (43.3)	21 (33.8)	10 (13.0)	28 (38.4)
Widening	11 (9.2)	12 (19.5)	51 (67.0)	29 (39.8)
Closing, both ends	2 (1.6)	6 (9 7)	6 (8.0)	1 (1.3)
Total	120	62	76	73



VIIIth-nerve tumors entirely within the internal auditory meatus. All five were said to have a high-tone loss in the affected ear although only one showed significant findings on special tests. Their audiograms were not presented. In any event, the evidence suggests that a widening" pattern with a minimal pure-tone threshold difference between the ears may be an early clue to the presence of a retrocochlear lesion. However because unilateral high-tone loss is a fairly common occurrence—for example, with various kinds of noise exposure and with long-standing loss from childhood—the audiologist must be extremely chary in attributing it to retrocochlear involvement.

Finally closing-both-ends" patterns were confined primarily to the *Other Cochlear Lesion* and *Retrocochlear Lesion* groups (Table 6 and Fig. 5), and were infrequent even there. Although they occurred with about equal probability in the two groups, they nevertheless should alert the audiologist to possible retrocochlear involvement.

It seems appropriate here to consider the groups individually and relate the pure-tone findings to those reported in the literature. For the *Menière's Disease* group, low-tone involvement (250 and 500 Hz) prevailed. Only in the few instances of widening and closing-both-ends patterns were the low tones less involved than the high tones. These results agree with the observations of Ophelm & Flottorp (1957), Lindsay (1960) and Schuknecht (1963) that low-tone loss is a *predominant* feature in Menière's disease. At the same time, there is no essential disagreement with the statement of Hallpike & Hood (1959) that in Menière's disease there may be high-tone loss, low-tone loss, or loss throughout the frequency range. Nor is there any contradiction to Goodman's (1965) observation of a great number of sharp peaks and dips in the affected ears. Peaks and dips were particularly noticeable in the constricting patterns.

Regarding the *Other Cochlear Lesion* group, the similarity of their patterns to the patterns of the *Menière's Disease* group doubtless reflects hydrops in many of the patients despite absence of the episodic vertigo required for a diagnosis of Menière's disease. Williams et al., (1950) and Lindsay & Schulthess (1858) have described patients with low-tone loss and certain other characteristics that should permit the diagnosis of endolympatic hydrops in the absence of vertigo. Day (1963) stated that the cochlear symptoms usually precede the vestibular symptoms in Menière's disease and suggested that treatment should begin with the *first cochlear symptoms in order to reverse the* pure-tone loss and to prevent vestibular symptoms from developing.

For the *Retrocochlear Lesion* group, the widening" patterns clearly predominated. Because high-tone involvement shown by the widening patterns is usually synonymous with falling configurations for the affected ear realistic comparisons with other studies can be made. Goodman (1957) found most configurations to be either flat or falling in a series of 18 patients with VIIIth-nerve lesion. Dix & Hallpike (1960) depicted the *pure-tone* configurations of 95 patients with VIIIth-nerve lesion. most configurations were falling; five were rising; several were flat, and some were not easily classifiable. Parker et al. (1968) in a series of 49 patients with retrocochlear lesion, found no characteristic shape to the curve, but some tendency for greater loss in the higher frequencies Johnson (1968) reported that, of 168 patients with acoustic neuromas, the pure-tone configurations revealed a high-

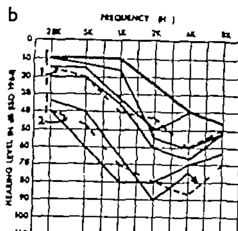


Fig 5 Examples of closing both-ends" patterns, *Othe Cochlear Lesion* and *Retrocochlear Lesion* groups. Normal hearing in the better ear (*b*) Examples of closing both-ends patterns, *Other Cochlear Lesion* and *Retrocochlear Lesion* groups.

tone loss in 64% a flat loss in 20% a low tone loss in 8% and a trough-shaped loss in the remaining 8% Accordingly the predominance of widening" patterns for our *Retrocochlear Lesion* group finds support in these four studies.

Two major patterns emerged for the *Sudden Loss* group one involving primarily the high tone range and the other involving the low tone range Comparisons with other surveys flounder here because of differences in portrayal and interpretation Hallberg (1956) Sheehy (1960) and Bosatra & DeStefan (1961) seem to agree however that hearing impairment in sudden loss may occur in any part of the frequency range

In summarizing the pure-tone findings it may be said that they are of definite value as alerting signs in the localization of lesion. In the absence of von Recklinghausen s disease, cochlear lesion is suggested with bilateral pure tone loss. In unilateral pure tone loss cochlear lesion is suggested with constricting" and closing" patterns. Constricting" patterns seem unique to hydrops of the labyrinth. Closing patterns suggest hydrops except in cases of sudden loss

In the absence of a history of sudden loss, *retrocochlear involvement is suggested* by total unilateral loss and by a widening" pure tone pattern. Retrocochlear involvement is also suggested by a closing both ends pattern and by a parallel pattern with a minimal difference between the ears (on the order of 10 to 25 dB)

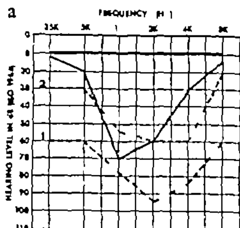
Speech Discrimination Scores

In general speech discrimination scores of patients with Menière s disease worsen as hearing loss for pure tones becomes more severe. Goodman (1965) using the Rush–Hughes recordings of the Harvard PB50 lists, found a Pearson product moment correlation of 0 84 between the discrimination loss and the pure tone average for 42 patients with Menière s disease In the present survey for discrimination losses on the CID W 22 lists and Fletcherian pure-tone

verages, Pearson product-moment correlations of 0.74 and 0.77 were obtained in samples comprising the first 72 *Menière's Disease* patients and the first 60 *Other Cochlear Lesion* patients.

For the *Retrocochlear Lesion* group, scatter diagrams showed an obvious lack of correlation between the two measures. For the *Sudden Loss* group, meaningful correlations were precluded by a high proportion of 0% scores (which skewed the score distribution) and by a predominance of severe losses (which skewed the hearing level distribution).

The speech discrimination scores were obtained by monitored live voice presentation at a comfortable loudness level for the patient, usually 40 dB above his speech reception threshold, except in cases of a tolerance problem. The predictive value of the scores was reduced somewhat by the use of live-voice presentation, and we had to keep in mind a conclusion by Goodman (1965) that "In the temporal course of Menière's disease, hearing level for tones and discrimination loss for speech vary independently of one another in a significant proportion of cases". Nevertheless, our test score data seemed of interest, especially because our report includes patients with cochlear lesions as well as patients with retrocochlear lesions, in contrast to other reports that have dealt with one group or the other.



The procedure was first to inspect scatter diagrams of W 22 test scores versus the Fletcherian pure-tone averages. This was done for the combined *Menière's Disease* and *Other Cochlear Lesion* groups (N 137) employed in the above Pearson product-moment correlations and for 60 *Retrocochlear Lesion* patients who had already taken the speech discrimination test at the time these correlations were obtained. A clear dichotomy between the scores of the *Retrocochlear Lesion* group and the scores of the combined *Menière's Disease + Other Cochlear Lesion* group emerged at an average pure-tone level of approximately 50 dB—the amount of overlap between the scores of the two groups increasing progressively as threshold level increased. Accordingly, for purposes of prediction, attention was focused on scores at the lower levels (better thresholds) as shown in Fig. 6.

It may be seen that when W 22 scores below 48% occur for patients with Fletcherian averages less than 40 dB, retrocochlear involvement can be predicted with high confidence. Since the two patients in the *Menière's Disease + Other Cochlear Lesion* group who scored between 32% and 38% within the 40–43 dB level were 75 and 65 years old, the possibility of exceptional cases among the elderly should be entertained. Other exceptions might be patients with sharply-falling configurations through the speech range—for example, slopes 20 dB or greater per octave from 500 to 4 000 Hz. Two patients in the *Other Cochlear Lesion* group were omitted from Fig. 6 because of such extreme slopes beginning at 500 Hz. Fig. 6 shows, incidentally, that a high discrimination score at any of these levels does not necessarily rule out retrocochlear involvement.

The above observations were conservative for the reasons already mentioned, and the wise audiologist will doubtless exercise judgment in individual instances. For example, with Fletcherian averages under 24 dB and fairly flat configurations through 2 000 Hz, he may suspect retrocochlear involvement with W 22 scores as high as 80%, or perhaps even a few points higher, when the opposite ear shows a score within a few points of 100%. Also, he may suspect retrocochlear involvement with scores close to 0%, except in cases of severe hearing loss and provided that there is no history of sudden onset. For example, of all 182 patients in the combined *Menière's Disease* and *Other Cochlear Lesion* groups for whom special tests were done, only two scored 0%. Of these, one had a Fletcherian average of 60 dB, and the other 80 dB. Altogether only 14 of the 182 scored below 20%; the Fletcherian averages for these 14 ranged from

The Fletcherian average refers to the average of the best two of the three speech frequency thresholds—500, 1 000, and 2 000 Hz.

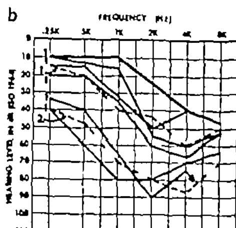

Fig 5 Examples of closing-both-ends patterns, *Other Cochlear Lesion* and *Retrocochlear Lesion* groups. Normal hearing in the better ear (*b*) Examples of closing-both-ends patterns, *Other Cochlear Lesion* and *Retrocochlear Lesion* groups.

tone loss in 64% a flat loss in 20% a low tone loss in 8% and a trough-shaped loss in the remaining 8% Accordingly the predominance of "widening" patterns for our *Retrocochlear Lesion* group finds support in these four studies.

Two major patterns emerged for the *Sudden Loss* group one involving primarily the high-tone range and the other involving the low tone range Comparisons with other surveys flounder here because of differences in portrayal and interpretation Hallberg (1956) Sheehy (1960) and Bosatra & DeStefan (1961) seem to agree however that hearing impairment in sudden loss may occur in any part of the frequency range

In summarizing the pure-tone findings, it may be said that they are of definite value as alerting signs in the localization of lesion In the absence of von Recklinghausen's disease cochlear lesion is suggested with bilateral pure-tone loss In unilateral pure tone loss cochlear lesion is suggested with constricting" and closing patterns. Constricting" patterns seem unique to hydrops of the labyrinth. Closing" patterns suggest hydrops except in cases of sudden loss.

In the absence of a history of sudden loss, retrocochlear involvement is suggested by total unilateral loss and by a widening" pure-tone pattern. Retrocochlear involvement is also suggested by a closing both ends" pattern, and by a parallel pattern with a minimal difference between the ears (on the order of 10 to 25 dB)

Speech Discrimination Scores

In general speech discrimination scores of patients with Menière's disease worsen as hearing loss for pure tones becomes more severe. Goodman (1965) using the Rush–Hughes recordings of the Harvard PB50 lists, found a Pearson product moment correlation of 0 84 between the discrimination loss and the pure-tone average for 42 patients with Menière's disease In the present survey for discrimination losses on the CID W 22 lists and Fletcherian pure tone

Alternate binaural loudness balance (ABLB)

The ABLB test for loudness recruitment was administered by presenting short-duration (approximately one second) tones of the same frequency alternately from one ear to the other with approximately a one-second interval between presentations. The frequencies selected were those showing a normal threshold for one ear (within 25 dB of audiometric zero) and a difference of at least 20 dB between the thresholds for the two ears.

For approximately 70% of the patients, the Fowler (1950) technique was followed, in which the tone of fixed intensity was presented to the better ear. At each of several successive 20-dB intensity levels above the threshold in the better ear several pairings of the tone were given. The patient reported verbally for each pairing whether the tone in the poorer ear was louder softer or the same in loudness as the tone in the better ear. The examiner through a bracketing procedure, found the level in the poorer ear at which the tone was judged to be equal in loudness to the tone in the better ear. When this procedure had been completed at several successive 20-dB levels in the better ear a laddergram was drawn which indicated the presence or absence of recruitment. Examples are shown in Fig. 7.

For 30% of the patients, the tone of fixed intensity was presented to the poorer ear (Jerger & Harford, 1960; Jerger 1962). A tone at a level 20 dB above the poorer-ear threshold was paired with tones at varying levels above the threshold for the better ear until a level was found at which the tone was judged to be equally loud in the two ears (see Fig. 8 for examples). In some patients the fixed tone was presented at a level 40 dB, as well as 20 dB, above the poorer ear threshold.

The ABLB test was usually done at two or three frequencies in the 250- to 4 000-Hz range. In most of the cases where the better ear served as the reference for the loudness matches, the completed laddergrams permitted a ready discernment of the presence or absence of recruitment. Occasionally however the laddergram was not completed because of audiometric limits or because recruitment was clearly evident after only two or three loudness matches. In these instances and in the few instances where recruitment was not immediately evident by inspection of the laddergram, the intensity ranges spanning the equal loudness growth for each ear were compared, and recruitment was presumed to be present when the intensity range for the better ear was at least twice that for the poorer ear. The same procedure in judging presence or absence of recruitment was followed for patients in whom the poorer ear served as the reference. No effort was made to define "partial" versus "complete" recruitment.

In Table 8 (*a–d*) a "Yes" was recorded in the loudness recruitment present column when recruitment was shown at one or more frequencies. Throughout the series, it was noted that when recruitment was present at one testable frequency it was typically present at others. When exceptions to this occurred, they were generally found among the *Retrocochlear Lesion* and *Sudden Loss* patients. In the few instances where only one frequency was tested, whether because of time limitations or because only one frequency was testable, the result for this one freqency was recorded in the table. If recruitment was absent, a "No" was recorded in the table. A blank space in the table indicates one of several possibilities: that no frequencies were testable, that the patient unreliable in his loudness judgments, or that the test simply was not done.

Short increment sensitivity index (SISI)

The SISI test was administered in the manner suggested by Jerger Shedd & Harford (1959) with slight modifications described by Owens (1965). A tone was presented to the affected ear at a level 20 dB above threshold at a given frequency with appropriate masking in the better ear and the patient was asked to signal whenever he heard a superimposed in-

55 dB to 80 dB Thus, with Fletcherian averages under 55 dB scores below 20%—especially scores of 0%—would be strongly suspected. Again, judgment should be tempered for elderly patients or patients with extremely sharp slopes in the speech-frequency range

It must be emphasized that the above interpretations are based only on the use of W 22 lists. The differences in interpretation necessitated by the use of other test lists were presented by Carhart in 1965

Regarding the pertinent literature, Schuknecht & Woellner (1955) seem to have been the first to note that a patient with VIIIth nerve lesion may show a reduction in speech discrimination ability that is grossly disproportionate to the degree of pure tone loss. Of two patients whom they reported, one scored only 16% despite normal pure-tone hearing in the speech-frequency range, and the other scored 0% despite only a 42 dB reduction in pure tone sensitivity Goodman (1957) described similar findings in several patients and concluded that a severe speech discrimination loss with normal pure tone thresholds suggests an intracranial lesion. Johnson (1968) reported scores ranging from 0% to 100 with most of them below 30% in 167 patients with retrocochlear lesions. A number of patients scored less than 30% even with normal pure tone thresholds

The Special Tests and their Interpretation

The special test battery comprised the Alternate Binaural Loudness Balance (ABLB) the Short Increment Sensitivity Index (SISI) a tone decay test, and Bekesy tracings.

Alternate binaural loudness balance (ABLB)

The ABLB test for loudness recruitment was administered by presenting short-duration (approximately one second) tones of the same frequency alternately from one ear to the other with approximately a one-second interval between presentations. The frequencies selected were those showing a normal threshold for one ear (within 25 dB of audiometric zero) and a difference of at least 20 dB between the thresholds for the two ears.

For approximately 70% of the patients, the Fowler (1950) technique was followed, in which the tone of fixed intensity was presented to the better ear. At each of several successive 20-dB intensity levels above the threshold in the better ear several pairings of the tone were given. The patient reported verbally for each pairing whether the tone in the poorer ear was louder softer or the same in loudness as the tone in the better ear. The examiner through a bracketing procedure, found the level in the poorer ear at which the tone was judged to be equal in loudness to the tone in the better ear. When this procedure had been completed at several successive 20-dB levels in the better ear a laddergram was drawn which indicated the presence or absence of recruitment. Examples are shown in Fig. 7.

For 30% of the patients, the tone of fixed intensity was presented to the poorer ear (Jerger & Harford, 1960; Jerger 1962). A tone at a level 20 dB above the poorer-ear threshold was paired with tones at varying levels above the threshold for the better ear until a level was found at which the tone was judged to be equally loud in the two ears (see Fig. 8 for examples). In some patients the fixed tone was presented at a level 40 dB, as well as 20 dB above the poorer ear threshold.

The ABLB test was usually done at two or three frequencies in the 250- to 4 000-Hz range. In most of the cases where the better ear served as the reference for the loudness matches, the completed laddergrams permitted a ready discernment of the presence or absence of recruitment. Occasionally however the laddergram was not completed, because of audiometric limits or because recruitment was clearly evident after only two or three loudness matches. In these instances and in the few instances where recruitment was not immediately evident by inspection of the laddergram, the intensity ranges spanning the equal loudness growth for each ear were compared, and recruitment was presumed to be present when the intensity range for the better ear was at least twice that for the poorer ear. The same procedure in judging presence or absence of recruitment was followed for patients in whom the poorer ear served as the reference. No effort was made to define "partial" versus complete recruitment.

In Table 8 (*a–d*) a "Yes" was recorded in the loudness recruitment present column when recruitment was shown at one or more frequencies. Throughout the series, it was noted that when recruitment was present at one testable frequency it was typically present at others. When exceptions to this occurred, they were generally found among the *Retrocochlear Lesion* and *Sudden Loss* patients. In the few instances where only one frequency was tested, whether because of time limitations or because only one frequency was testable, the result for this one freqency was recorded in the table. If recruitment was absent, a "No" was recorded in the table. A blank space in the table indicates one of several possibilities: that no frequencies were testable, that the patient unreliable in his loudness judgments, or that the test simply was not done.

Short increment sensitivity index (SISI)

The SISI test was administered in the manner suggested by Jerger, Shedd & Harford (1959) with slight modifications described by Owens (1965). A tone was presented to the affected ear at a level 20 dB above threshold at a given frequency with appropriate masking in the better ear and the patient was asked to signal whenever he heard a superimposed in-

55 dB to 80 dB Thus, with Fletcherian averages under 55 dB scores below 20%—especially scores of 0%—would be strongly suspected Again, judgment should be tempered for elderly patients or patients with extremely sharp slopes in the speech frequency range

It must be emphasized that the above interpretations are based only on the use of W 22 lists. The differences in interpretation necessitated by the use of other test lists were presented by Carhart in 1965

Regarding the pertinent literature, Schuknecht & Woellner (1955) seem to have been the first to note that a patient with VIIIth nerve lesion may show a reduction in speech discrimination ability that is grossly disproportionate to the degree of pure tone loss. Of two patients whom they reported, one scored only 16% despite normal pure-tone hearing in the speech-frequency range, and the other scored 0% despite only a 42 dB reduction in pure-tone sensitivity Goodman (1957) described similar findings in several patients and concluded that a severe speech discrimination loss with normal pure-tone thresholds suggests an intracranial lesion Johnson (1968) reported scores ranging from 0% to 100% with most of them below 30% in 167 patients with retrocochlear lesions. A number of patients scored less than 30% even with normal pure tone thresholds

The Special Tests and their Interpretation

The special test battery comprised the Alternate Binaural Loudness Balance (ABLB) the Short Increment Sensitivity Index (SISI) a tone decay test, and Bekesy tracings.

Alternate binaural loudness balance (ABLB)

The ABLB test for loudness recruitment was administered by presenting short-duration (approximately one second) tones of the same frequency alternately from one ear to the other with approximately a one second interval between presentations. The frequencies selected were those showing a normal threshold for one ear (within 25 dB of audiometric zero) and a difference of at least 20 dB between the thresholds for the two ears.

For approximately 70% of the patients, the Fowler (1950) technique was followed, in which the tone of fixed intensity was presented to the better ear. At each of several successive 20-dB intensity levels above the threshold in the better ear several pairings of the tone were given. The patient reported verbally for each pairing whether the tone in the poorer ear was louder softer or the same in loudness as the tone in the better ear. The examiner through a bracketing procedure, found the level in the poorer ear at which the tone was judged to be equal in loudness to the tone in the better ear. When this procedure had been completed at several successive 20-dB levels in the better ear a laddergram was drawn which indicated the presence or absence of recruitment. Examples are shown in Fig. 7

For 30% of the patients, the tone of fixed intensity was presented to the poorer ear (Jerger & Harford, 1960 Jerger 1962). A tone at a level 20 dB above the poorer-ear threshold was paired with tones at varying levels above the threshold for the better ear until a level was found at which the tone was judged to be equally loud in the two ears (see Fig. 8 for examples). In some patients the fixed tone was presented at a level 40 dB, as well as 20 dB, above the poorer ear threshold.

The ABLB test was usually done at two or three frequencies in the 250- to 4 000-Hz range. In most of the cases where the better ear served as the reference for the loudness matches, the completed laddergrams permitted a ready discernment of the presence or absence of recruitment. Occasionally however the laddergram was *not completed*, because of audiometric limits or because recruitment was clearly evident after only two or three loudness matches. In these instances and in the few instances where recruitment was not immediately evident by inspection of the laddergram, the intensity ranges spanning the equal loudness growth for each ear were compared, and recruitment was presumed to be present when the intensity range for the better ear was at least twice that for the poorer ear. The same procedure in judging presence or absence of recruitment was followed for patients in whom the poorer ear served as the reference. No effort was made to define "partial" versus "complete" recruitment.

In Table 8 (*a–d*) a "Yes" was recorded in the loudness recruitment present column when recruitment was shown at one or more frequencies. Throughout the series, it was noted that when recruitment was present at one testable frequency it was typically present at others. When exceptions to this occurred, they were generally found among the *Retrocochlear Lesion* and *Sudden Loss* patients. In the few instances where only one frequency was tested, whether because of time limitations or because only one frequency was testable, the result for this one freqency was recorded in the table. If recruitment was absent, a "No" was recorded in the table. A blank space in the table indicates one of several possibilities: that no frequencies were testable, that the patient unreliable in his loudness judgments, or that the test simply was not done.

Short increment sensitivity index (SISI)

The SISI test was administered in the manner suggested by Jerger Shedd & Harford (1959) with slight modifications described by Owens (1965) A tone was presented to the affected ear at a level 20 dB above threshold at a given frequency with appropriate masking in the better ear and the patient was asked to signal whenever he heard a superimposed in-

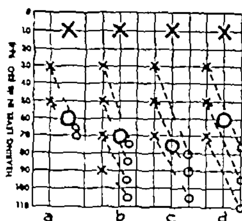

Fig 7 Laddergrams for ABLB when the tone of fixed intensity is presented to the better ear Large X's and O s are thresholds. Loudness recruitment is present in (*a*) (*b*), (*c*) but absent in (*d*).

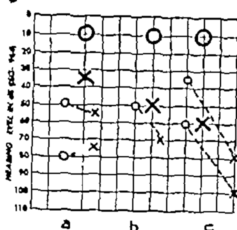

Fig 8 Laddergrams for ABLB when the tone of fixed intensity is presented to the poorer ear Large X's and O s are thresholds. Loudness recruitment present at (*a*) and (*b*), but absent at (*c*).

crement of 1 dB A Yes" was recorded in Table 8 under the SISI column when he scored 60% or higher at one or more *frequencies* Otherwise, a No" was recorded. Although the SISI test was usually given at two or three frequencies circumstances occasionally per mitted the testing of only one frequency As with recruitment, however it had been noted that a high SISI score at one frequency was typically accompanied by high scores at other frequencies, given comparable threshold levels. Therefore if a valid test result was obtained for only one frequency it was recorded in the table

It must be borne in mind that the SISI test often produces low scores with mild threshold losses despite known cochlear involvement (Owens, 1965) In the present survey scores below 60% at frequencies showing threshold levels less than 45 dB were discounted at the same time, scores of 60% or higher at low levels were interpreted as a reflection of cochlear involvement.

In addition the SISI test is sometimes complicated by tone decay in that a patient may lose the carrier tone but continue responding to the 1-dB increments. Hughes (1968) has reported that of a series of 18 patients who demonstrated this behavior three had retrocochlear lesions Therefore, caution must be employed in interpreting the results in these instances.

Whereas the ABLB test was used to explore for the presence of recruitment, the SISI test was used to explore for hyperacuity to small changes in intensity at a given level above threshold A Yes" in either column (Table 8) was interpreted as evidence of cochlear involvement.

Tone decay

The tone decay test employed was one described by Owens in 1964 based on the work of Hood (1955) For a given frequency a tone was presented at a steady intensity 5 dB above the threshold in the poorer ear and the patient was asked to hold up his hand (or press steadily on a signal button) as long as he heard the tone. If the tone faded before a minute had elapsed he was given a 20-sec rest, and the tone was presented at the next higher 5-dB level. This sequence continued until he heard the tone for a minute or until he had listened to the tone at four presentation levels, each 5 dB higher than the preceding one. The time in seconds during which the tone could be heard at each presentation level was noted on the audiogram under the test frequency Examples of various tone decay patterns are shown in Table 7

Table 7 *Examples of tone decay patterns*

Numbers composing tone decay patterns are in seconds

Levels above threshold (dB)	Type I*	Type II				Atypical	Type III					
		A	*B*	*C*	*D*							
5	60	20	9	15	12	3	4	3	2	15	3	36
10		60	32	25	19	10	2	5	12	25	8	40
15			60	40	29	14	5	8	15	20	13	38
20				60	37	19	3	12	10	24	13	42

* No significant tone decay

Type I means no significant tone decay—that is, the patient was able to sustain a tone for 60 sec at 5 dB above threshold. Type II means *that the patient*, after showing decay at the 5-dB level above threshold, was able to sustain the tone for increasingly longer periods of time —on the average of eight seconds or more— at successively *higher levels of presentation* 5 dB apart. Type III means that the patient failed to show any essential increase—less than four seconds, on the average—in the length of time he could sustain the tone with each 5-dB increment "Atypical" means that the tone was heard on the average of four to seven seconds longer with each successive 5-dB increment.

The letter categories in Table 7 are generally not used clinically but they are of aid in describing different kinds of Type II patterns. The patterns are described as follows. "A" the tone decays at 5 dB above threshold, but the 1 min criterion is met at 10 dB "B" the tone decays at 5 and 10 dB above threshold, but is heard noticeably longer at the 10-dB level and for one minute at 15 dB "C" the tone decays at the 5- 10- and 15-dB levels—but is heard noticeably longer with each successive 5-dB increment—and is heard for one minute at 20 dB "D" the tone decays at 5 10 15 and 20 dB above threshold, but is heard for a longer time, on the average of eight seconds or more with each successive 5-dB increment. The "atypical" pattern is synonymous with the "E" pattern of Owens (1964)

White noise masking was introduced to the better ear at a level considered to be *sufficient* even if four or five increments of 5 dB were necessary to complete the test at a given frequency.[1] Shimizu (1969) has reported inducing tone decay (and high SISI scores) in normal and conductively involved ears by applying a moderate amount of contralateral white noise masking. He *attributed the phenomenon* to a neural-interaural interference. Regardless, opposite ear masking was considered to be necessary for the Tone Decay test (as well as for the SISI test) in all instances of unilateral loss in our survey and the results must be interpreted with this understanding. The major question regarding tone decay in cochlear versus retrocochlear involvement—namely whether the tone can be sustained for longer periods *with increased intensity*—was believed not to have been complicated by contralateral masking.

The tone decay test was given at several frequencies, usually those exhibiting the greatest threshold loss. A "Yes" was placed under the appropriate column in Table 8 if at one or more frequencies, the patient showed a Type III pattern. A "No" was inserted if, at all of several frequencies tested, the patient was able to sustain the tone for one minute at any of the four or five intensity levels, or failing this, if he was able to sustain the tone for increasingly longer periods of time—on the aver

[1] *In actual practice, it seems best to limit the tone decay test to four or five intensity increments at each frequency. Further testing sometimes introduces complicating factors such as patient fatigue, confusion, or the necessity for increasing opposite-ear masking.*

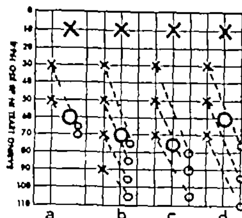

Fig 7 Laddergrams for ABLB when the tone of fixed intensity is presented to the better ear Large X's and O s are thresholds. Loudness recruitment is present in (*a*), (*b*), (*c*), but absent in (*d*).

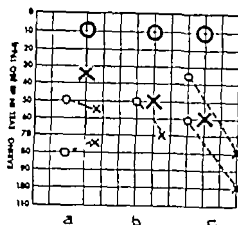

Fig 8 Laddergrams for ABLB when the tone of fixed intensity is presented to the poorer ear Large X's and O s are thresholds. Loudness recruitment present at (*a*) and (*b*), but absent at (*c*).

crement of 1 dB A Yes" was recorded in Table 8 under the SISI column when he scored 60% or higher at one or more frequencies. Otherwise, a No" was recorded. Although the SISI test was usually given at two or three frequencies, circumstances occasionally per mitted the testing of only one frequency As with recruitment, however it had been noted that a high SISI score at one frequency was typically accompanied by high scores at other frequencies, given comparable threshold levels. Therefore, if a valid test result was obtained for only one frequency it was recorded in the table

It must be borne in mind that the SISI test often produces low scores with mild threshold losses despite known cochlear involvement (Owens, 1965) In the present survey scores below 60% at frequencies showing threshold levels less than 45 dB were discounted at the same time, scores of 60% or higher at low levels were interpreted as a reflection of cochlear involvement.

In addition, the SISI test is sometimes com plicated by tone decay in that a patient may lose the carrier tone but continue responding to the 1-dB increments. Hughes (1968) has reported that of a series of 18 patients who demonstrated this behavior three had retro-cochlear lesions. Therefore, caution must be employed in interpreting the results in these instances.

Whereas the ABLB test was used to ex plore for the presence of recruitment, the SISI test was used to explore for hyperacuity to small changes in intensity at a given level above threshold. A Yes" in either column (Table 8) was interpreted as evidence of cochlear involvement

Tone decay

The tone decay test employed was one de scribed by Owens in 1964 based on the work of Hood (1955) For a given frequency a tone was presented at a steady intensity 5 dB above the threshold in the poorer ear and the pa tient was asked to hold up his hand (or press steadily on a signal button) as long as he heard the tone. If the tone faded before a minute had elapsed, he was given a 20-sec rest, and the tone was presented at the next higher 5-dB level This sequence continued until he heard the tone for a minute or until he had listened to the tone at four presentation levels, each 5 dB higher than the preceding one The time, in seconds, during which the tone could be heard at each presentation level was noted on the audiogram under the test frequency Ex amples of various tone decay patterns are shown in Table 7

*"Cochlear" special test results.

Stadler E-800 Békésy audiometer provided a tone of gradually changing intensity at the rate of 2.5 dB per second and gradually changing frequency at the rate of one octave per minute. For some patients, sweep-frequency tracings over the range from 250 to 4 000 Hz were obtained, first for an interrupted-tone stimulus (2.5 interruptions per second), then for a continuous-tone stimulus. For other patients, fixed frequency tracings were obtained for interrupted and continuous-tone stimuli at octave-interval frequencies within the same range (250–4 000 Hz). For still other patients, both sweep- and fixed-frequency tracings were obtained. Practice was always given on the non-test ear to ascertain that the task could be accomplished. Subjects were instructed to respond just to the tone, (1) because an occasional patient experienced the "tone perversion" mentioned earlier and (2) because extraneous stimuli seemed to be present at the high-intensity limits of the equipment.

With a substantial hearing loss in the test ear white-noise masking in the better ear was usually set at a level around 100 dB SPL. With near-normal hearing in the test ear the noise level was set at 80 or 90 dB, SPL. The intent here was to guard against overmasking while at the same time ensuring sufficient masking should there be a marked shift in the continuous-tone tracing.

Although both sweep- and fixed-frequency tracings were obtained for a number of patients, time limitations usually necessitated a choice between the two. Problems with the Jerger (1960) classification of the sweep-frequency tracings reported by Owens in 1964 continued in evidence as data accumulated, leading to a preference for the fixed-frequency tracings in the latter part of the survey. For example, at a point in the survey when sweep tracings had been obtained for 76 of the *Ménière's Disease* patients and for 27 of the *Other Cochlear Lesion* patients, a number of patterns were seen in which the continuous-

age of eight seconds or more—at each higher intensity level. Where atypical" patterns occurred the results at other frequencies decided the insertion in Table 8

For some patients, a screening test was given The test tone was first presented at a level 10 dB above threshold If the patient failed to sustain the tone for a minute it was presented once again, after a 20-second rest, at a level 10 dB higher If the 60-sec criterion was met at either level a No" was inserted in the table. If the results were questionable, the regular test was given

It should be noted that with any test of tone decay the tonal stimulus may change, for an occasional patient, to a buzz hiss" or other noise instead of disappearing completely This phenomenon, mentioned by Sorensen (1962) and noted by Harbert & Young (1964 *a* 1964 *b*) was termed tone perversion" by Parker Decker & Richards (1968) Its significance is yet to be determined. A few patients in our survey like the one described by Simmons & Dixon (1964) could not discern a tone at all Tone perversion occurred most frequently in the *Sudden Loss* group occasionally in the *Retrocochlear Lesion* group and rarely in the *Menière s Disease* and *Other Cochlear Lesion* groups.

Some patients lost" the test tone, but were able to tell when the switch was turned off typically they reported then that they had still been hearing something. No clear explanation for this phenomenon can be given at present. In a few of these instances, tone perversion seemed to have been operating, while in others the tone was described as having merged with tinnitus. From the patients descriptions, it seemed that the test tone and the tinnitus had become indistinguishable, but that the tinnitus had somehow been altered in the process. Consequently when the tone was turned off they became aware of another change in the tinnitus. For most patients in the *Menière s Disease* and *Other Cochlear Lesion* groups, Type II patterns typically emerged despite tinnitus that is, at successively higher presentation levels, the test tone took longer to blend with the tinnitus. In a few of the cochlear lesion patients however an apparently loud tinnitus interfered to produce Type III tone decay patterns at certain frequencies. Such results were of course not valid The data reported in the present survey are based on the premise that the patient, as instructed, ceased responding when the test tone disappeared.

Békésy tracings

Békésy tracings were obtained as described by Jerger (1960 *a*) and Owens (1964) A Grason–

from the midpoint of the (*I*) tracing width (19 9 dB for the *Menière's Disease group* 19.5 dB for the *Other Cochlear Lesion group*)—the pattern was considered *uninterpretable*. When audiometer limits were reached after a shift *of more* than 20 dB the tracing was considered to be significant because the (*C*) tracing with a cochlear loss would then be expected to stabilize only about five times in 100 were sufficient room available. Occasionally the (*C*) tracing for the *Retrocochlear Lesion* group was uninterpretable at 250 Hz, but interpretable at higher frequencies where the audiometer limits were wider In Table 8, then, a "Yes" was recorded under Significant Békésy Shift" when (*C*) reached audiometer limits after a shift of 20 dB or more.

The problem of masking with sweep-frequency tracings deserves special mention. On the one hand, the masking may be of sufficient intensity for the (*I*) tracing of the test ear but not for the (*C*) tracing when a downward shift occurs (since the intensity of the test tone then increases until it overcomes the opposite-ear masking) a shadow tracing—a pseudo Type IV—may thus be produced. On the other hand, a high level of opposite-ear masking may through some as yet unexplained mechanisms, selectively shift (*C*) without concomitantly shifting (*I*)

Apropos is a recent study by Blegvad (1968) who used the Békésy audiometer (Grason Stadler *E-800*) used in our study and followed the same general test procedure except that he employed *inserts* instead *of* standard earphones for white-noise masking. He observed the Békésy tracings for the affected ears of 31 patients with unilateral sensorineural loss under conditions of no masking and of 80-dB masking, being careful to rule out shadow curves in the unmasked condition and overmasking in the masked condition. He found noticeable differences in the relation between (*I*) and (*C*) under the two conditions. For example, *the* masking often changed Type I tracings to Type II, Type II to Type IV and, in three patients, Type I to Type IV Also, the masking frequently changed the relation between (*I*) and (*C*) with respect to the amplitude of the tracings. No explanation of these changes was offered. Although Blegvad stated in effect that these findings fail to detract from the diagnostic significance of Békésy audiometry his findings are nevertheless unsettling to the conscientious audiologist. The Békésy *results of the* present survey must be interpreted on the basis that masking was employed *for all subjects*. The extent of pure-tone sensorineural loss in *most of the* affected ears *made it unlikely that over*masking occurred, even with the white noise at a *maximum tolerable* level (usually 100 to 110 dB, SPL) in the non-test ear The possibility that overmasking occurred with near normal pure-tone levels in the affected ear cannot be ruled out entirely

Two other troubling aspects of masking with sweep-frequency tracings are: (*a*) the most appropriate level of masking changes as the frequency range is traversed, and (*b*) a high level of masking for the 4 or 5 min required to complete a sweep may be discomforting and possibly harmful to the patient.

The use of *fixed-frequency tracings* tended to reduce problems of interpretation. In these tracings for patients with cochlear lesions, either (*C*) and (*I*) overlapped (Jerger Type I) or (*C*) shifted downward slightly with narrowing of width and stabilization in a position parallel to (*I*) (Jerger Type II). When fixed-frequency Békésy tracings had been obtained for 55 *Menière's Disease* patients and 43 *Other Cochlear Lesion* patients, the shifts were measured from the midpoint of each (*I*) tracing to the midpoint *of the* corresponding (*C*) tracing. The means of the shifts and their *S.D.s* appear in Table 10 In calculating the *means*, 0-dB shifts (Jerger Type *I*) were not counted. For the frequencies 500, 1 000 2 000 and 4 000 Hz, the means for the *Menière's Disease* group were 7.3 7.5 8.8, and 8 8 dB S.D.s were 4.7 2.8, 3.3, and 4 0 dB. The means for *the Other Cochlear Lesion* group at the same *frequencies* were 7 4 8.6, 9.3 and 10.4 dB S.D.s were 3.6, 3 4 4.5 and 5 6 dB. The

t.

tone tracing (C) shifted downward from the interrupted-tone tracing (I) at or below 250 Hz and remained below the (I) tracing over the entire frequency range to 4 000 Hz. As (C) *shifted, it narrowed noticeably in* width compared to (I) These patterns were the Jerger Type IV that have been associated with retrocochlear involvement. They appeared in 20 of the 76 tracings for *Menière s Disease* patients, and in eight of the 27 tracings for the *Other Cochlear Lesion* patients, but in none of 50 tracings obtained for the *Retrocochlear Lesion* patients. Such patterns are thus clearly consistent with *cochlear* involvement. Hughes Winegar & Crabtree (1967) have also concluded that the Jerger Type IV patterns as well as the Jerger Type II patterns, generally represent cochlear impairment.

In addition, other patterns only briefly mentioned in the Jerger (1960) classification system appeared in eight of the same 76 patients in the *Menière s Disease* group and in one of the same 27 patients in the *Other Cochlear Lesion* group In these patterns, the (*C*) tracing shifted downward from the (*I*) tracing in the low tone range (beginning around 250 Hz) and rejoined the (*I*) tracing in the middle or high-tone range A narrowing of tracing width typically accompanied the (C) shift. Generally these patterns were associated with pure-tone configurations showing noticeably greater low tone than high tone impairment. No pattern of this kind occurred in the 50 sweep tracings obtained for the *Retrocochlear Lesion* group

Accordingly the definition of Owens (1964) was followed regarding Type II (cochlear) sweep tracings. the (*C*) training may drop below (*I*) at any point in the frequency range (250–4 000 Hz) typically with concomitant narrowing It then characteristically remains essentially parallel to (*I*) but occasionally may rejoin (*I*)" The interpretation of the amount of shift in such tracings remains a problem, however Hughes et al (1967) attached a retrocochlear interpretation to tracings in which (*C*) parallels (*I*) at a distance greater than 20 dB Adherence to this limitation would misclassify as retrocochlear" two of our *Other Cochlear Lesion* and one of our *Sudden Loss* patients. The latter experienced a sudden loss in his operated ear several months after stapedectomy Other special test findings for all three patients were cochlear" and the sweep Békésy (*C*) tracings which were narrower in width than (*I*) ran parallel to (*I*) at a distance between 20 and 25 dB below Accordingly 25 dB might be a more practical limit beyond which retrocochlear lesion would be suspected. This corresponds to approximately three standard deviations below the mean shift of (*C*) measured for a group of cochlear lesion patients—see next section. (It is assumed that we are not discussing a transient (*C*) shift, perhaps greater than 30 dB that may occur at one point after which (*C*) approaches (*I*) These seemingly erratic shifts with narrowing of width occurred in two of our *Other Cochlear Lesion* patients.) On the other hand, we would suspect retrocochlear involvement whenever narrowing fails to occur with a shift of (*C*) since in only two or three instances did the (*C*) tracings of the *Menière s Disease* + *Other Cochlear Lesion* patients fail to narrow perceptibly

Another problem with the sweep-frequency tracings was that when hearing impairment was severe (*C*) often reached audiometer limits after only a slight shift. It would have been inaccurate to label such a tracing a Jerger Type III (retrocochlear) pattern when the tracing might have stabilized to a Type II (cochlear) pattern given more time and space. For the 76 *Menière s Disease* patients and the 27 *Other Cochlear Lesion* patients, the amount of shift was measured at *the point of greatest* shift. Measurements were from the midpoint of (*I*) to the midpoint of (*C*) For the *Menière s Disease* group, the mean of these shifts was 10 5 dB and the standard deviation (S.D) was 4 7 dB for the *Other Cochlear Lesion* group the mean was 10 7 dB and the S D 4 4 dB (Table 9)

Accordingly when (*C*) reached audiometer limits after shifting less than two S.D s from the mean shift—that is less than about 20 dB

fect, that the fixed-frequency tracings were chosen in all cases of disagreement.

Regarding the relative widths of the (*I*) and (*C*) tracings, (*C*) almost invariably narrowed in the process of shifting the small amounts that indicated cochlear involvement. This narrowing occurred in both the sweep- and fixed-frequency tracings. In the sweep-frequency shifts significant for retrocochlear involvement, (*C*) usually progressed steadily downward to audiometer limits, so that narrowing of tracing width, although it occurred sometimes, could not be measured in the manner employed for the tracings that stabilized. For 37 patients in the *Retrocochlear Lesion* group whose fixed-frequency tracings indicated retrocochlear involvement, (*C*) shifted steadily to audiometer limits (Jerger Type III) at all frequencies tested (20 patients). Type III shifts occurred at some frequencies while at other frequencies (*C*) shifted and then stabilized (eight patients) and Type III shifts failed to occur but (*C*) shifted an amount significant for retrocochlear involvement and then stabilized (nine patients). Where (*C*) shifted significantly and then stabilized, narrowing of tracing width occurred in about one-half of the instances. In these last 17 of the 37 patients, "cochlear" tracings (Jerger Type II, i.e., insignificant shifts) were sparsely scattered throughout the records.

Fixed-frequency patterns in which (*C*) stabilizes after shifting an amount that would indicate retrocochlear involvement can reasonably be labeled Type IV whether or not narrowing occurs. The use of such labeling would recognize Hopkinson's (1966) plea that some sort of standardization based on Jerger's original descriptions be maintained, if classifications must be used. When (*C*) *fails to narrow* in the process of stabilizing, retrocochlear involvement should be suspected even though the amount of shift does not meet the significance criterion. Such tracings might be labeled "atypical."

Results of Special Tests

The complete results for the special tests are shown in Table 8 (a–d). As mentioned previously, a number of patients did not receive all tests. Occasionally testing was discontinued owing to illness or fatigue of the patient. In other instances, limitations of time prevented the completion of all the tests and the patient failed to return as requested. In still other instances, the pure-tone levels precluded valid ABLB and SISI tests and, finally, some patients could not perform reliably on all tests. Since these circumstances are no doubt common to most clinics, with the consequent necessity of sometimes basing impressions on incomplete test findings, it seemed appropriate to include all patients who had given reliable responses for at least one of the special tests.

A helpful factor in dealing with an incomplete test battery was the close agreement (see Table 8) between the ABLB and SISI tests and also between the Tone Decay and Békésy tests. This agreement had been noted previously for the ABLB and SISI tests by Yantis & Decker (1964) and Owens (1965) and for the Tone Decay and the Békésy tests by Harbert & Young (1964 *b*) and Owens (1965).

Both the ABLB and the SISI tests were given to 151 patients, some from each group. The results agreed in 144 instances—that is, both were designated "Yes" or both were designated "No" in Table 8. In most of the disagreements, one or both of the tests gave indefinite results, e.g., questionable recruitment, or SISI scores slightly below 60%. Both the Tone Decay and the Békésy tests were given to 174 patients, some from each group, and the results agreed in 163 instances. In seven of the 11 patients showing disagreement, the Tone

Table 9 *Békésy shifts with cochlear lesions (sweep-frequency tracings)*

Group	No of tracings	Mean shift (dB)	S.D (dB)
Menière s Disease	76	10.5	4 7
Other Cochlear Lesion	27	10.7	4 4

* The shift for each tracing was measured at the point of greatest shift and from midpoint of (*I*) to midpoint of (*C*).

Ns for the tracings differed among the frequencies because the same frequencies were not tested for all patients. At 250 Hz, too few patients were tested to justify the computation of means and standard deviations.

In the *Menière s Disease* group one patient showed shifts of 50 dB and 60 dB at 2 000 and 4 000 Hz. In the *Other Cochlear Lesion* group one patient showed shifts of 33 dB and 28 dB at 250 and 500 Hz. These two patients were judged to be atypical and were excluded from Table 10

The mean shifts and the S D.s of the *Other Cochlear Lesion* groups were employed in the interpretation of fixed frequency tracings.[1] For a given frequency a shift was considered significant of retrocochlear involvement when it fell more than three S.D s below the mean shift. In round numbers, shifts of three S D.s from the mean were synonymous with shifts of 18 19 23 and 27 dB measured from the mid points of the (*I*) tracings at 500 1 000 2 000 and 4 000 Hz A Yes was recorded in Table 8 when a significant shift occurred at one or more frequencies. For patients showing no shifts, or shifts less than 18 19 23 or 27 dB before stabilization a No" was recorded in Table 8 The interpretation differed slightly when (*C*) reached audiometer limits. If (*C*) shifted more than two S D s from the mean for any test frequency before reaching audiometer in limits the shift was considered significant and a Yes" was inserted in Table 8. If (*C*) shifted less than two S D.s before reaching audiometer limits the shift was considered to be uninterpretable for the test frequency In round numbers shifts of two S D.s for 500 1 000 2 000 and 4 000 Hz were 15 15 18, and 22 dB from the midpoints of the (*I*) tracings.

Inevitably the question arose whether to use the fixed or sweep-frequency tracings in localization of lesion when both had been done When both tests were interpretable results usually pointed to the same decision regarding a "Yes" or No" in Table 8 Both kinds of tracings were obtained for 37 *Menière s Disease* patients with the results agreeing in 36 for 16 patients in the *Other Cochlear Lesion* group with the results agreeing in 14 for 36 patients in the *Retrocochlear Lesion* group with the resulting agreeing in all but four and for 19 *Sudden Loss* patients with the results agreeing in all but one. In all instances when the results disagreed the fixed tracings indicated a Yes" and the sweep tracings a No in Table 8

When no interpretable results were obtained, a blank was left in the table When disagreement occurred between interpretable sweep- and fixed frequency tracings, we selected the Yes" result for the table This meant, in ef

Table 10 *Békésy shifts with cochlear lesions (fixed-frequency tracings)*[a]

Frequencies (Hz)	No. of tracings	Mean shift (dB)	S.D (dB)
Menière s Disease			
500	28	7 3	4.7
1 000	46	7 5	2.8
2 000	52	8.8	3.3
4 000	45	8.8	4.0
Other Cochlear Lesion			
500	23	7 4	3 6
1 000	29	8.6	3.4
2 000	36	9.3	4.5
4 000	38	10.4	5 6

[a] Measured from midpoint of (*I*) to midpoint of (*C*).

[1] Since these means and S.D s were consistently greater than those for the *Menière s D sease* group, it was reasoned that est mates of sign ficant shifts based on data for the *Other Cochlear Lesion* group would apply to the *Menière s Disease* group as well.

fect, that the fixed-frequency tracings were chosen in all cases of disagreement.

Regarding the relative widths of the (*I*) and (*C*) tracings, (*C*) almost invariably narrowed in the process of shifting the small amounts that indicated cochlear involvement. This narrowing occurred in both the sweep- and fixed-frequency tracings. In the sweep-frequency shifts significant for retrocochlear involvement, (*C*) usually progressed steadily downward to audiometer limits, so that narrowing of tracing width, although it occurred sometimes, could not be measured in the manner employed for the tracings that stabilized. For 37 patients in the *Retrocochlear Lesion* group whose fixed-frequency tracings indicated retrocochlear involvement: (*C*) shifted steadily to audiometer limits (Jerger Type III) at all frequencies tested (20 patients). Type III shifts occurred at some frequencies while at other frequencies (*C*) shifted and then stabilized (eight patients) and Type III shifts failed to occur but (*C*) shifted an amount significant for retrocochlear involvement and then stabilized (nine patients). Where (*C*) shifted significantly and then stabilized, narrowing of tracing width occurred in about one-half of the instances. In these last 17 of the 37 patients, "cochlear" tracings (Jerger Type II, i.e., insignificant shifts) were sparsely scattered throughout the records.

Fixed-frequency patterns in which (*C*) stabilizes after shifting an amount that would indicate retrocochlear involvement can reasonably be labeled Type IV whether or not narrowing occurs. The use of such labeling would recognize Hopkinson's (1966) plea that some sort of standardization based on Jerger's original descriptions be maintained, if classifications must be used. When (*C*) fails to narrow in the process of stabilizing, retrocochlear involvement should be suspected even though the amount of shift does not meet the significance criterion. Such tracings might be labeled "atypical".

Results of Special Tests

The complete results for the special tests are shown in Table 8 (*a–d*). As mentioned previously a number of patients did not receive all tests. Occasionally testing was discontinued owing to illness or fatigue of the patient; in other instances, limitations of time prevented the completion of all the tests and the patient failed to return as requested; in still other instances, the pure-tone levels precluded valid ABLB and SISI tests; and, finally, some patients could not perform reliably on all tests. Since these circumstances are no doubt common to most clinics, with the consequent necessity of sometimes basing impressions on incomplete test findings, it seemed appropriate to include all patients who had given reliable responses for at least one of the special tests.

A helpful factor in dealing with an incomplete test battery was the close agreement (see Table 8) between the ABLB and SISI tests and also between the Tone Decay and Békésy tests. This agreement had been noted previously for the ABLB and SISI tests by Yantis & Decker (1964) and Owens (1965) and for the Tone Decay and the Békésy tests by Harbert & Young (1964 *b*) and Owens (1965).

Both the ABLB and the SISI tests were given to 151 patients, some from each group. The results agreed in 144 instances—that is, both were designated "Yes" or both were designated "No" in Table 8. In most of the disagreements, one or both of the tests gave indefinite results, e.g., questionable recruitment, or SISI scores slightly below 60%. Both the Tone Decay and the Békésy tests were given to 174 patients, some from each group, and the results agreed in 163 instances. In seven of the 11 patients showing disagreement, the Tone

[a] "Cochlear" special test results.

Decay test indicated retrocochlear involvement, while the Békésy test indicated cochlear involvement in two of these seven, the disagreement occurred only at 4 000 Hz. In the remaining four of the 11 patients, the reverse was shown, the Tone Decay test indicating cochlear involvement, and the Békésy retrocochlear involvement.

Accordingly with the two tests of each pair largely in agreement regarding cochlear versus retrocochlear lesion, the results shown in Table 8 were distilled into those of Table 11 for clearer exposition In that table, discrepancies between the ABLB and SISI and between the Tone Decay and Békésy tests are indicated by an "X"

Of 120 *Menière's Disease* patients, "Yes-No" results occurred for 112, "-No" for five, "Yes-X" for one, and "Yes-Yes" for two. Of the 62 *Other Cochlear Lesion* patients "Yes-No" results occurred in 55 "Yes-Yes" in two, "X-No" in two, and "Yes-X" in three. The combined results for all 182 patients with presumed cochlear involvement were "Yes-No" in 167 "Yes-Yes" in four "X-No" in two, "Yes-X" in four and "-No" in five. "Yes-No" results are thus characteristic of cochlear involvement

Special tests were given to 78 patients in the *Retrocochlear Lesion* group (Table 11 *c*) This group included the five previously mentioned patients who were omitted from the pure-tone pattern section because their pure tone results could not be classified. Excluded from this group because they had had no special tests were three patients who had been included in the pure-tone section "No-Yes" results predominated, occurring in 32 of the 78 patients. Note that 13 patients showed neither ABLB nor SISI test results. The special test results for these 13 were "-Yes" for 12 and "-No" for one. Seven of the 13 had normal or near normal hearing in the affected ear rendering standard ABLB and SISI testing invalid. In the remaining six of the 13 neither the ABLB nor the SISI tests could be done for the various clinical reasons mentioned earlier Six other patients, "No-" in Table 11 *c* had neither the Békésy nor the Tone Decay test. Other results for the *Retrocochlear Lesion* group were "No-No" in three "Yes-Yes" in three, "X-Yes" in three, "No-X" in two and "Yes-No" in 16

According to Table 11 it seemed reasonable to class pairings of "Yes-X" "X-No" "-No" and "Yes-No" as "cochlear" and to class pairings of "X-Yes" "-Yes" "No-" "No-X" and "No-Yes" as "retrocochlear" Thus where an X occurred for one pair of tests, the findings were classed according to the results for the other pair "Yes-Yes" and "No-No" pairings were classed as "mixed cochlear-retrocochlear" In summary then two patients in the *Menière's*

Disease group and two patients in the *Other Cochlear Lesion* group, all "Yes-Yes" showed mixed cochlear-retrocochlear findings—that is, 2.2% of the 182 patients in the combined cochlear lesion groups. All the rest (97.8%) showed cochlear signs. On the other hand, 17 of the 78 patients (22%) in the *Retrocochlear Lesion* group, one with a "X-No" pairing and 16 with "Yes-No" pairings, showed cochlear findings. Fifty-five patients (70%) in the *Retrocochlear Lesion* group showed retrocochlear signs, and the remaining six patients (8%) showed mixed cochlear-retrocochlear findings. The fact that mixed cochlear-retrocochlear findings were relatively infrequent in the cochlear lesion patients compared to the retrocochlear lesion patients suggests the advisability of stressing the likelihood of retrocochlear involvement whenever mixed results are seen.

In the *Sudden Loss group*, 55 patients (75%) showed cochlear results (51 "Yes-No," two "X-No" and two "Yes-X"), 12 patients (17%) showed retrocochlear results (eight "No-Yes" three "No-X" and one "X-Yes") and six (8%) showed mixed cochlear-retrocochlear results (all "Yes-Yes").

Of major interest are the 17 patients in the Retrocochlear Lesion group whose special test results were completely cochlear. These patients are marked by asterisks in Tables 8-c and 11-c. In the one patient (with a brain-stem glioma) who had only a Békésy test, minimal hearing loss precluded standard ABLB and SISI testing. Although both sweep and fixed Békésy tracings were Type I, retrocochlear involvement was correctly predicted for this patient when the discrimination score for the poorer ear on a W-22 list distorted by noise was dramatically reduced by 74 points in contrast to a reduction of only 18 points for the opposite ear (see discussion of Goetzinger & Angell, 1965). All results for the other 16 patients indicated cochlear involvement. Recruitment was present at all testable frequencies in all but two patients, these showing complete recruitment at one frequency and no recruitment at others. (The recruitment findings for these two patients, in retrospect, should have been interpreted as suggestive of retrocochlear involvement—see Discussion.) SISI scores were typically 100%. Tone Decay was Type I or II and Békésy tracings, whether fixed or sweep, showed no significant shifts of the (C) tracing. The slight (C) shifts that did occur were accompanied by a noticeable narrowing of width. Sweep Békésy tracings were obtained for nine of these 16 patients, fixed tracings for six, and both kinds for one. In the nine sweep tracings, shifts of (C) occurred after 500 Hz, if at all. Thus the tracings fitted Jerger's (1960) Type II definition. The discrimination scores all seemed consistent with the extent and pattern of pure tone loss. It is noteworthy that *all* special tests were misleading.

A variety of retrocochlear lesions were involved in these 17 patients: sheath tumors (10), arachnoid cyst (4), meningioma (1), brain-stem glioma (1) and granulomatous meningitis (1).

Other patients of special interest in the *Retrocochlear Lesion* group are some of those for whom neither the ABLB nor the SISI tests could be done in the ordinary sense. Groupings for discussion are as follows: (1) those with unilateral retrocochlear involvement whose pure-tone patterns could not be classified according to our system (four patients) and (2) those who demonstrated bilateral Type *III* tone decay or significant Békésy (C) shifts with either unilateral pure-tone loss or normal hearing for pure tones bilaterally (three patients).

(1) Two of the patients with *unclassifiable* pure-tone audiograms had normal and equal pure-tone hearing bilaterally. One of these had multiple sclerosis and the other an epidermoid cyst of the pons involving cranial nerves V and VII–XI on the left. For both patients, Békésy fixed-frequency tracings supported normal hearing in one ear but indicated retrocochlear involvement in the other. It should be noted that the *sweep* Békésy (*I*) and (*C*) tracings *for the affected* ears overlapped, showing nothing of significance. Surprisingly, 2 days after pneumoencephalographic air studies, the fixed-frequency Békésy (*I*) and (*C*) tracings over

lapped completely for the affected ear in the patient with the cyst since this patient was highly reliable it was thought that the air studies had possibly displaced the cyst.

The third patient of this group, with a meningioma in the tentorial notch extending to involve the VIIIth nerve on the right side, had a mild bilateral high-tone loss showing no consistent difference between the ears. For the right ear Type III tone decay occurred at several frequencies sweep- and fixed frequency Békésy tracings showed significant shifts to audiometer limits, and a W 22 score of 20% occurred with a pure-tone speech-frequency average of 18 dB For the left ear neither tone decay nor Békésy (*C*) shifts occurred and the speech discrimination score was 98%

The fourth patient of this group had a mild, gradually sloping pure tone loss in the right ear associated with a brain-stem glioma. Pure tone thresholds for the left ear when compared with those for the right ear were the same (15 dB) at 250 and 500 Hz, 15 to 20 dB better at 1 000 and 2 000 Hz, and 35 to 40 dB poorer at 4 000 and 8 000 Hz, thus producing a reversal of configurations The history revealed exposure to gunfire and bomb blasts Special test findings for the left ear were consistent with normal hearing in the low and middle frequencies, and cochlear involvement at 4 000 Hz. For the right ear Tone Decay was Type II at 500 Hz and Type III from 1 000 through 4 000 Hz. Although the sweep (*I*) and (*C*) Békésy tracings interwove (Type I) fixed Békésy tracings showed (*C*) shifting slightly at 500 Hz, inconclusively at 1 000 Hz, and significantly at 2 000 and 4 000 Hz.

(2) Of the three patients in this second group one with brain-stem glioma demonstrated a mild gradually sloping, pure tone loss in the left ear and pure-tone hearing just within normal in the right. W 22 scores were 0% in the left ear 68% in the right Both ears showed Type III Tone Decay and significant Békésy shifts at several frequencies. The second patient, with multiple sclerosis, showed tone decay at all frequencies in both ears in the 250–4 000 Hz range although she had normal and equal pure tone hearing bilaterally In each ear Tone Decay was Type III for one frequency and either Type II or atypical for the rest. Although the sweep Békésy (*I*) and (*C*) tracings overlapped completely the fixed-frequency (*C*) tracings for both ears shifted slightly at all frequencies and significantly at 2 000 Hz. Little or no narrowing occurred. W 22 scores were 96% bilaterally The third patient, with a left cerebellopontine angle epidermoid cyst extending through the foramen magnum to the right, showed for the left ear a severe pure tone loss, 0% speech discrimination Type III tone decay and significant Békésy shifts. Although the right ear showed normal pure tone hearing and 96% speech discrimination, Type III tone decay occurred in that ear at 2 000 and 4 000 Hz.

In connection with this second group, a patient described by Reger (1962) should be mentioned. This patient demonstrated marked Békésy shifts bilaterally although bilateral pure tone hearing was within the normal range. A massive pinealoma was found at operation, and the Békésy tracings reverted to normal after its removal.

Obviously the findings for these two small groups of patients point up the importance of bilateral testing for at least tone decay and Békésy shifts, despite normal pure tone hearing, when patients are referred on suspicion of retrocochlear involvement Furthermore, they clearly show that the Békésy fixed-frequency tracings are more sensitive to retrocochlear involvement than the sweep-frequency tracings (see also Katinsky & Toglia, 1968)

During the period of this survey many patients referred by otolaryngological neurological and neurosurgical services for the ruling out of retrocochlear involvement of the auditory pathways were found to have normal hearing for pure tones and speech with no evidence of tone decay or significant Békésy shifts. Some of these patients showed Type II Békésy tracings, as might have been expected from the report of Price et al. (1965) No particular

meaning was attached to these minimal shifts with respect to the question of cochlear versus retrocochlear involvement. A number of patients were also tested for a difference between the two ears with respect to loudness growth and performance on a difficult test of speech discrimination employing noise or low-pass filtering (see Jerger 1960 Goetzinger & Angell, 1965 and Hodgson, 1967). Results of these tests were negative for retrocochlear involvement. Common symptoms of these patients were vestibular disturbances, headaches, and facial tics. Complete medical and neurological work-ups were negative with respect to neoplasm, and in most instances no final diagnosis was made, or the problem was described as "emotionally based". On the other hand, an occasional patient in this group was found to have a tumor that seemingly should have involved the auditory pathways, but such involvement was not reflected in the Tone Decay or Békésy tests. (ABLB testing, when performed showed nothing of significance). Special tests of greater power appear to be needed here (See, for example Sanchez Longo et al. 1957 Bocca, 1958 Eichel et al 1966 Jerger 1960 Katz et al., 1963).

With respect to the *Sudden Loss* patients, the question arises whether a retrocochlear lesion in the form of a neoplasm might have been present in the 18 patients whose special test results suggested either retrocochlear or mixed cochlear-retrocochlear involvement. Twelve of the 18 had had roentgenograms of the internal auditory meati, all of which had been clearly within normal limits. A marked improvement in hearing occurred subsequently in one of the six who had had no roentgenograms, and findings on caloric tests and neurological examination were normal in one other patient. Of the remaining four who had not had roentgenograms, three had had a severe hearing loss for several years with no other symptoms. In this connection, it should be noted that in all 18 patients, the hearing loss was severe at onset.

Thus, at present we believe it unlikely that a retrocochlear lesion in the form of neoplasm would be associated with sudden hearing loss as defined in this survey even though the special test results might sometimes be the same as those indicating a neoplasm (see Jerger et al 1961).

As yet there is no real agreement on the etiology or localization of lesion in sudden loss. Until there is, the audiologist must qualify to the best of his ability the "retrocochlear" special test results that are sometimes encountered. At present he can only suggest that such findings do appear occasionally in patients with a history of sudden loss, and that, regardless of the special test findings, neoplasm has been a rare occurrence in several reported series. Thus the history of onset assumes major importance.

Relation between ABLB/SISI and Tone Decay/Békésy

The close agreement between the ABLB and SISI and between the Tone Decay and Békésy tests with respect to site of lesion has already been discussed. In this section we will consider the agreement between the two pairs of tests.

For the combined *Ménière's Disease + Other Cochlear Lesion* group, the ABLB SISI results and the Tone Decay Békésy results showed good agreement regarding site of lesion. As may be seen in Table 11 discrepancies ("Yes-Yes") occurred in only four instances (2%). In two of the four ABLB/SISI and Tone Decay/Békésy were done at the same frequencies. In the other two ABLB/SISI were done at certain frequencies and Tone Decay/Békésy at other frequencies. The findings for these two patients were unusual in that, as mentioned previously the indications for site

lapped completely for the affected ear in the patient with the cyst since this patient was highly reliable it was thought that the air studies had possibly displaced the cyst.

The third patient of this group with a meningioma in the tentorial notch extending to involve the VIIIth nerve on the right side, had a mild bilateral high-tone loss showing no consistent difference between the ears For the right ear Type III tone decay occurred at several frequencies, sweep- and fixed frequency Békésy tracings showed significant shifts to audiometer limits, and a W 22 score of 20% occurred with a pure tone speech-frequency average of 18 dB For the left ear neither tone decay nor Békésy (C) shifts occurred and the speech discrimination score was 98%

The fourth patient of this group had a mild, gradually sloping, pure tone loss in the right ear associated with a brain stem glioma. Pure-tone thresholds for the left ear when compared with those for the right ear were the same (15 dB) at 250 and 500 Hz, 15 to 20 dB better at 1 000 and 2 000 Hz, and 35 to 40 dB poorer at 4 000 and 8 000 Hz, thus producing a reversal of configurations. The history revealed exposure to gunfire and bomb blasts Special test findings for the left ear were consistent with normal hearing in the low and middle frequencies and cochlear involvement at 4 000 Hz. For the right ear Tone Decay was Type II at 500 Hz and Type III from 1 000 through 4 000 Hz Although the sweep (I) and (C) Békésy tracings interwove (Type I) fixed Békésy tracings showed (C) shifting slightly at 500 Hz, inconclusively at 1 000 Hz, and significantly at 2 000 and 4 000 Hz.

(2) Of the three patients in this second group one with brain-stem glioma, demonstrated a mild gradually-sloping, pure tone loss in the left ear and pure-tone hearing just within normal in the right. W 22 scores were 0% in the left ear 68% in the right Both ears showed Type III Tone Decay and significant Békésy shifts at several frequencies. The second patient, with multiple sclerosis, showed tone decay at all frequencies in both ears in the 250–4 000 Hz range, although she had normal and equal pure tone hearing bilaterally In each ear Tone Decay was Type III for one frequency and either Type II or atypical for the rest. Although the sweep Békésy (I) and (C) tracings overlapped completely the fixed frequency (C) tracings for both ears shifted slightly at all frequencies and significantly at 2 000 Hz. Little or no narrowing occurred W 22 scores were 96% bilaterally The third patient, with a left cerebellopontine-angle epidermoid cyst extending through the foramen magnum to the right, showed for the left ear a severe pure tone loss, 0% speech discrimination Type III tone decay and significant Békésy shifts. Although the right ear showed normal pure-tone hearing and 96% speech discrimination Type III tone decay occurred in that ear at 2 000 and 4 000 Hz.

In connection with this second group, a patient described by Reger (1962) should be mentioned. This patient demonstrated marked Békésy shifts bilaterally although bilateral pure tone hearing was within the normal range. A massive pinealoma was found at operation, and the Békésy tracings reverted to normal after its removal

Obviously the findings for these two small groups of patients point up the importance of bilateral testing for at least tone decay and Békésy shifts despite normal pure-tone hearing, when patients are referred on suspicion of retrocochlear involvement Furthermore, they clearly show that the Békésy fixed frequency tracings are more sensitive to retrocochlear involvement than the sweep-frequency tracings (see also Katinsky & Toglia, 1968)

During the period of this survey many patients referred by otolaryngological, neurological, and neurosurgical services for the ruling out of retrocochlear involvement of the auditory pathways were found to have normal hearing for pure tones and speech, with no evidence of tone decay or significant Békésy shifts Some of these patients showed Type II Békésy tracings as might have been expected from the report of Price et al. (1965) No particular

between the ears or by unreliability of test results, especially if tone perversion was involved.

On their return visits, patients with subsequently verified retrocochlear lesions frequently showed a worsening of pure-tone thresholds. Of ten *Retrocochlear Lesion* patients who returned for retests before operation, the following downward shifts in pure-tone thresholds were noted: the shifts were fairly even across the frequency range (four patients) the shifts were confined primarily to the high frequencies (two patients) the shifts were confined to the low (250–500 Hz) frequencies (two patients) and the shifts occurred at selective frequencies (one patient). No shifts occurred in one patient. Thus, although downward shifts in hearing, shown on repeated examination, are strongly indicative of retrocochlear involvement (see Bucy & Ismat, 1961) little reliance can be placed upon the *pattern* of shift. The pattern of the shift further loses significance when one notes (see Goodman, 1965) that successive changes in pure-tone configurations for Menière's disease (cochlear) patients reveal no characteristic pattern that is, a given pattern of shift between two successive tests might occur with either cochlear or retrocochlear lesions.

Irrespective of the pattern of shift, though, it would seem unwise to consider a progressively downward shift in hearing, per se to be an invariable sign of retrocochlear lesion in the form of neoplasm. For example, factors such as labyrinthine otosclerosis and systemic, inflammatory or viral disorders affecting the cochlea would have to be considered, and, as Davis (1962) points out, toxic or metabolic factors may interfere with VIIIth-nerve function.

Discrimination scores for the above ten retested *Retrocochlear Lesion* patients decreased variably In four of the ten, however scores decreased by 70 points or more, greatly out of proportion to the pure-tone shift, thereby providing strong evidence for retrocochlear involvement.

With respect to the special tests, a few *Retrocochlear Lesion* patients showed predominantly cochlear signs on one visit and predominantly retrocochlear signs on a visit several months later Conversely one patient with a sheath tumor had definite retrocochlear signs on one visit and definite cochlear signs on the next.

One of the two Menière's Disease patients, who showed "Yes–Yes findings in Table 11 revealed completely cochlear signs on the same tests five months later accompanied by pure tone improvement on the order of 10 to 15 dB. Finally in two of the *Sudden Loss* patients, special test results changed from retrocochlear to cochlear in conjunction with noticeable improvement in pure-tone thresholds. In this connection, Harbert & Young (1964 *a*) have reported on two patients with sudden loss, one with cochlear and the other with retrocochlear special test findings, both of whom experienced a complete recovery of normal hearing.

In any event, the important point is that questionable findings regarding site of lesion can often be resolved when hearing is retested after a few weeks or months. Changes may occur in pure-tone thresholds, in discrimination scores, or in the patterning of special test results.

Constellations of Test Results

Doubtless, information regarding site of lesion accrues when the special test findings are viewed together with pure-tone patterns and speech discrimination scores. For example, of

of lesion were generally consistent from frequency to frequency for all of the special tests in the *Menière's Disease + Other Cochlear Lesion* group given threshold levels that permitted valid ABLB and SISI testing. Different indications from frequency to frequency regarding site of lesion were found more often among the *Retrocochlear Lesion* and *Sudden Loss* groups.

Among the *Retrocochlear Lesion* group discrepancies between ABLB/SISI and Tone Decay/Békésy occurred in six instances (8%)—three "Yes–Yes" and three "No–No" as shown in Table 11 c In one of the "Yes–Yes" patients, recruitment was shown at the only testable frequency of 4 000 Hz, Tone Decay and Békésy were not tested at 4 000 Hz, but gave Type III patterns at all lower frequencies. In the other two "Yes–Yes" patients ABLB/SISI and Tone Decay/Békésy were done at the same frequencies.

For two of the three "No–No patients the special tests were given at the same frequencies. Reliability may have been poor for these two however because one spoke no English and was ill during the testing, and the other a 13-year-old child had to be tested quite rapidly because of scheduling demands. The latter had a meningioma in the cerebellopontine angle associated with von Recklinghousen's disease, and the former a sheath tumor described as rising from the Vth, rather than from the VIIIth nerve The third patient who had an acoustic neurinoma and a marginal pure-tone loss in the affected ear showed *no* recruitment at 250 Hz, the only frequency that allowed valid ABLB Her Békésy tracings were Type II at all frequencies, 250–4 000 Hz.

Inter test discrepancies occurred in six of the *Sudden Loss* patients (8) All six were Yes–Yes" (Table 11) In three of the six "Yes–Yes" patients, ABLB/SISI and Tone Decay/Békésy were done at the same frequencies, and in the remaining three, at different frequencies.

In summary then discrepancies between the two pairs of tests, although relatively infrequent for all groups, occurred more often in the *Retrocochlear Lesion* and *Sudden Loss* groups (both 8%) than in the *Menière's Disease + Other Cochlear Lesion* group (2%). Consequently in the absence of a history of sudden loss, such discrepancies suggest the likelihood of retrocochlear lesion. In any event the occurrence of these discrepancies, even though they involved only 16 (5%) of the total 333 patients, emphasizes the importance of doing at least one of the tests in each pair preferably at the same three or four frequencies. Testing with the remaining special tests would depend upon the reliability and definitiveness of results on the first two tests.

Ordinarily the frequencies in the 500- to 4 000-Hz range that showed the greatest pure tone loss provided the most useful information Interestingly four patients in the *Retrocochlear Lesion* group showed retrocochlear auditory signs in the form of Type III tone decay and significant Békésy shifts at only one frequency—2 000 Hz in every case.

Changes in Hearing

When special test results were inconsistent regarding site of lesion, or when other grounds for suspicion of retrocochlear involvement arose, the patient was generally *asked* to return in a month or two for a repetition of the tests (unless he underwent an operation performed on the basis of non auditory symptoms and signs) Suspicion might have been engendered for example by a "widening" pure-tone pattern even though special test results were cochlear by a parallel" pure tone pattern accompanying a minimal (10–20 dB) difference

Table 12. *Patients with brain-stem lesion*

results often enough that a strong prediction of a small tumor cannot be made in the individual case.

With respect to site of retrocochlear lesion, the large majority of tumors were reported to be in the cerebellopontine angle, and the point of origin was the VIIIth nerve within the internal auditory meatus. Constellations of special test results seemed generally no different, however, when the tumors involving the VIIIth nerve in the cerebellopontine angle arose from a different origin, such as the Vth nerve.

More promising were attempts to differentiate between the lesions localized primarily to the VIIIth nerve and other lesions localized primarily to the brain stem (comprising the mid-brain, pons, and medulla oblongata) (see Bunis, 1965). Table 12 presents the test results for 11 patients with lesions of the brain stem—six with brain-stem glioma, four with multiple sclerosis, and one with a pontine cyst.

Because the four patients with multiple sclerosis had lesions not verified surgically their inclusion in the "brain-stem lesion" group should be justified. It is known that many patients with multiple sclerosis have normal hearing for pure-tones (von Leden & Horton, 1948) and for tests of recruitment and tone decay (Dayal, Tarantino & Swisher 1966). When hearing impairment occurs, it may be manifest in various ways. Simpkins (1961) reported a characteristic pure-tone pattern in which the low tones were affected more than the high tones, but Dayal et al. (1966) found no such pattern. Recruitment is typically absent (Dix, 1965) tone decay may be present even with normal pure-tone hearing (Dayal, Tarantino & Swisher 1966). Finally all audiologic signs and symptoms may be completely reversible (Rose & Daley 1964 Dix, 1965).

Of our four patients with multiple sclerosis, one had a mild unilateral pure-tone loss with a

the 17 *Retrocochlear Lesion* patients who had cochlear test findings, 13 showed "widening" pure tone patterns three showed "closing both ends" patterns, and one showed a "closing" pattern A "widening pattern with cochlear results on the special tests occurred with a probability of 0 18 among the *Retrocochlear Lesion* patients, which was slightly greater than the probability of 0 13 among the *Menière s Disease + Other Cochlear Lesion* patients. Similarly a closing both ends" pattern with cochlear special test results occurred with a probability of 0 04 for the *Retrocochlear Lesion* group and with the same probability (0 04) for the *Menière s Disease + Other Cochlear Lesion* group Thus, the occurrence of a widening" or a "closing both ends" pattern despite coch lear special test findings suggests possible retrocochlear involvement. Even when non auditory symptoms and signs are absent, these patients should be followed carefully particularly when the history of onset is vague.

In other instances the pure-tone patterns may serve to increase confidence in the special test indications For example in only one instance (that of a patient with an arachnoid cyst) did a closing" pattern occur in combination with cochlear special test findings when a retrocochlear lesion was present On the other hand a "closing" pattern in combination with cochlear special test findings occurred in 73 of the 182 *Menière s Disease + Other Cochlear Lesion* patients. Similarly the "constricting pure-tone pattern in combination with cochlear special test findings occurred in 35 of the 182 patients with cochlear involvement and in none of the patients with retrocochlear involvement. Thus, cochlear involvement and the absence of retrocochlear involvement can be predicted with a high degree of confidence when a "closing" or constricting pure-tone pattern is combined with cochlear special test results.

The possible significance of a parallel" pure tone pattern occurring with a minimal dif ference in pure tone thresholds between the ears was discussed earlier Although these patterns alone should raise the question of possible retrocochlear lesion they of course achieve much greater significance when accompanied by Type III (or in some instances atypical) tone decay patterns, significant Békésy shifts, or marked reductions in speech discrimination

In an attempt to determine which inter test relations might predict type of lesion size of lesion, or specific site of lesion the test data and operative reports for the *Retrocochlear Lesion* patients were studied—with discouraging results. Operative reports were available for almost all of the 73 patients who had lesions involving the VIIIth nerve and who had taken the special tests. The data revealed no particular constellations of test results that could be correlated with type of lesion—that is, sheath tumor meningioma, cyst or brain-stem glioma.

Correlation attempts were also unrewarding with respect to size of lesion partly because information in the operative reports regarding tumor size was inadequate. It was evident, however that when all special test results indicated retrocochlear lesion large tumors sometimes accompanied mild pure-tone losses and small tumors sometimes accompanied severe losses, which suggests that tumor size cannot be pre dicted accurately from the pure tone level holding constant the special test results. A possible relation between size of tumor and consistency of the special tests in predicting retrocochlear lesion was suggested by Johnson (1968) He found that when some of the special tests pointed to cochlear rather than to retrocochlear involvement the tumor was often small Of our 17 patients in the *Retrocochlear Lesion* group whose special test results pointed to cochlear involvement ten had a sheath tu mor Of these ten, information regarding size of tumor was available for only seven all of whom had a moderate sensorineural loss in the affected ear The tumors were described in the operative reports as the size of a small lemon sizeable a large mass" moderate size" the size of a large pea 1 5 centimeters" and "one centimeter The first four descriptions seemed to indicate that large and moderate sized tumors produce inconsistent special test

the 17 *Retrocochlear Lesion* patients who had cochlear test findings, 13 showed "widening" pure-tone patterns three showed "closing both ends" patterns, and one showed a "closing" pattern. A "widening" pattern with cochlear results on the special tests occurred with a probability of 0 18 among the *Retrocochlear Lesion* patients, which was slightly greater than the probability of 0 13 among the *Menière s Disease + Other Cochlear Lesion* patients. Similarly a "closing both ends pattern with cochlear special test results occurred with a probability of 0 04 for the *Retrocochlear Lesion* group and with the same probability (0 04) for the *Menière's Disease + Other Cochlear Lesion* group Thus, the occurrence of a widening" or a "closing both ends" pattern despite cochlear special test findings suggests possible retrocochlear involvement. Even when non auditory symptoms and signs are absent these patients should be followed carefully particularly when the history of onset is vague

In other instances the pure tone patterns may serve to increase confidence in the special test indications For example, in only one instance (that of a patient with an arachnoid cyst) did a closing" pattern occur in combination with cochlear special test findings when a retrocochlear lesion was present. On the other hand, a "closing" pattern in combination with cochlear special test findings occurred in 73 of the 182 *Menière s Disease + Other Cochlear Lesion* patients Similarly the "constricting" pure tone pattern in combination with cochlear special test findings occurred in 35 of the 182 patients with cochlear involvement and in none of the patients with retrocochlear involvement. Thus, cochlear involvement, and the absence of retrocochlear involvement, can be predicted with a high degree of confidence when a "closing" or constricting" pure-tone pattern is combined with cochlear special test results.

The possible significance of a parallel" pure tone pattern occurring with a minimal difference in pure-tone thresholds between the ears was discussed earlier Although these patterns alone should raise the question of possible retrocochlear lesion they of course achieve much greater significance when accompanied by Type III (or in some instances atypical) tone decay patterns, significant Békésy shifts, or marked reductions in speech discrimination

In an attempt to determine which inter-test relations might predict type of lesion size of lesion, or specific site of lesion, the test data and operative reports for the *Retrocochlear Lesion* patients were studied—with discouraging results. Operative reports were available for almost all of the 73 patients who had lesions involving the VIIIth nerve and who had taken the special tests. The data revealed no particular constellations of test results that could be correlated with type of lesion—that is, sheath tumor meningioma, cyst or brain-stem glioma.

Correlation attempts were also unrewarding with respect to size of lesion, partly because information in the operative reports regarding tumor size was inadequate. It was evident, however that when all special test results indicated retrocochlear lesion, large tumors sometimes accompanied mild pure-tone losses and small tumors sometimes accompanied severe losses, which suggests that tumor size cannot be predicted accurately from the pure-tone level, holding constant the special test results. A possible relation between size of tumor and *consistency* of the special tests in predicting retrocochlear lesion was suggested by Johnson (1968) He found that when some of the special tests pointed to cochlear rather than to retrocochlear involvement, the tumor was often small Of our 17 patients in the *Retrocochlear Lesion* group whose special test results pointed to cochlear involvement, ten had a sheath tumor Of these ten information regarding size of tumor was available for only seven all of whom had a moderate sensorineural loss in the affected ear The tumors were described in the operative reports as the size of a small lemon" sizeable a large mass moderate size" the size of a large pea" 1.5 centimeters" and one centimeter" The first four descriptions seemed to indicate that large and moderate sized tumors produce inconsistent special test

Table 12. *Patients with brain-stem lesion*

Diagnosis	Pure-tone pattern	Ear	Pure-tone average (dB)	Speech discrimination (%)	Recruitment	Tone decay	Békésy shift
Brain-stem glioma	Widening	R	12	96 (78)	—	I & II	Insignificant

results often enough that a strong prediction of a small tumor cannot be made in the individual case.

With respect to site of retrocochlear lesion, the large majority of tumors were reported to be in the cerebellopontine angle, and the point of origin was the VIIIth nerve within the internal auditory meatus. Constellations of special test results seemed generally no different, however, when the tumors involving the VIIIth nerve in the cerebellopontine angle arose from a different origin, such as the Vth nerve.

More promising were attempts to differentiate between the lesions localized primarily to the VIIIth nerve and other lesions localized primarily to the brain stem (comprising the mid-brain, pons, and medulla oblongata) (see Busis, 1965). Table 12 presents the test results for 11 patients with lesions of the brain stem—six with brain-stem glioma, four with multiple sclerosis, and one with a pontine cyst.

Because the four patients with multiple sclerosis had lesions not verified surgically, their inclusion in the "brain-stem lesion" group should be justified. It is known that many patients with multiple sclerosis have normal hearing for pure-tones (von Leden & Horton, 1948) and for tests of recruitment and tone decay (Dayal, Tarantino & Swisher, 1966). When hearing impairment occurs, it may be manifest in various ways. Simpkins (1961) reported a characteristic pure-tone pattern in which the low tones were affected more than the high tones, but Dayal et al. (1966) found no such pattern. Recruitment is typically absent (Dix, 1965), tone decay may be present even with normal pure-tone hearing (Dayal, Tarantino & Swisher, 1966). Finally, all audiologic signs and symptoms may be completely reversible (Rose & Daley, 1964; Dix, 1965).

Of our four patients with multiple sclerosis, one had a mild unilateral pure-tone loss with

1. the brain-stem lesions of the present series, it seemed probable that either the cochlear nuclei were involved, or excrescence involved the VIIIth-nerve fibers in the cerebellopontine angle.

closing" pattern and another had a moderate unilateral pure tone loss with a "widening" pattern. Both of these two patients showed 0% SISI scores, Type III tone decay significant Békésy shifts and no recruitment in the affected ear the better ear was normal on all tests. The other two patients (mentioned earlier) had normal and equal hearing for pure tones bilaterally One of these two showed significant fixed frequency Békésy shifts in one ear and no shifts in the opposite ear (tone decay was not done) The other showed Type III tone decay *and significant Békésy shifts bilaterally* Thus, the special test results for all four did indicate retrocochlear involvement—unilaterally in three and bilaterally in one.

Most investigators believe that the lesion causing hearing impairment in multiple sclerosis is in the area of the cochlear nuclei von Leden & Horton (1948) quote Leidler (1917) who in a series of 13 consecutive cases, found pathologic confirmation that the disease does have a predilection for the region of the vestibular and cochlear nuclei Dix (1965) states that the lesion must lie distal to the cochlear nuclei and central to the neurilemmal-neurologlial junction of the VIIIth nerve" The evidence was taken to indicate that patients with multiple sclerosis were appropriately placed in the brain-stem lesion" group

It seemed profitable to compare the results for these 11 patients (13 ears) with 20 patients studies by Parker et al. (1968) although the comparison is somewhat precarious considering the differences in classification of patients and in test materials and terminology For the sake of comparison, it must be agreed (1) that tone decay" is employed in the same sense as the "pathologic adaptation" of Parker et al., (2) that the Type III decay classification can be applied to severe tone decay by Carhart's (1957) test (see the data of Sorensen 1962) and (3) that the Parker pontine" group corresponds to our brain stem lesion" group Parker et al. did include *patients with multiple* sclerosis in their pontine" group On the other hand, they included several patients not represented in our group, namely patients with a diagnosis of "vertebrobasilar artery insufficiency" The findings of both series indicated that brain-stem lesion is suggested when Type III tone decay and significant Békésy shifts accompany normal or near normal pure tone hearing. The suggestion of brain stem lesion is stronger when Type III tone decay or significant Békésy shift occurs bilaterally

Speech discrimination findings showed good agreement in that about half the patients with brain-stem lesion in each group had scores of 80% or better In contrast scores for patients with VIIIth-nerve lesion were generally much lower in each group A score of 80% or better was made by only four of the 26 patients with VIIIth nerve lesion who formed the control group in the Parker series and by only three of our 17 patients with sheath tumors whose hearing levels were comparable to those of our brain-stem lesion" group—that is, thresholds under 40 dB Fletcherian average. Caution must be exercised in drawing conclusions regarding speech discrimination scores because all findings were based on live voice testing using different tests According to the data of Epstein Giolas & Owens (1968) we would expect the Harvard PB-50 lists (Parker series) to be somewhat more difficult than the W 22 lists (our series) under any circumstances of presentation

Substantial disagreement occurred only with regard to recruitment. Unfortunately the numbers for comparison are small. In our series, one in four of the "brain-stem lesion" patients who took the ABLB test showed recruitment, as did 17 of 61 (approximately one in four) other patients in the *Retrocochlear Lesion* group In the Parker series however five of the eight "pontine" patients who took the test showed recruitment in contrast to only three of 17 patients in their VIIIth nerve lesion group. Their conclusion that recruitment occurs frequently in patients with brain stem lesion runs counter to our findings and to observations of Dix (1965) who reported that recruitment is typically absent in multiple sclerosis.

It can be stated, on the basis of the two series, that brain-stem lesion, as opposed to VIIIth-nerve lesion, is suggested when Type III tone decay results and/or significant Békésy shifts (1) occur bilaterally (?) occur unilaterally along with normal or near-normal pure-tone hearing, or (3) occur with high speech discrimination scores (on the order of 80% or higher) on the W 22 lists. The suggestion of brain-stem lesion as opposed to VIIIth-nerve lesion appears to be strongest in (1) and weakest in (3)

The relation between Tone Decay/Békésy and speech discrimination deserves mention. In our *Retrocochlear Lesion* group Type III tone decay or significant Békésy shifts in the speech frequency range were generally accompanied by extremely low speech discrimination scores, although high scores occurred on occasion. Extremely low discrimination scores were found infrequently in the absence of Type III tone decay or significant Békésy shifts. Thus the Tone Decay and Békésy (fixed frequency) tests seem to be more sensitive to retrocochlear involvement than the speech discrimination scores, at least insofar as the VIIIth-nerve and brain-stem lesions are concerned.

Reports by Goetzinger & Angell (1965) and Hodgson (1967) suggest that with cortical lesion, reduction in speech discrimination may be the more sensitive indicator That is, they found reduced discrimination on difficult tests (as by frequency distortion) on the side opposite to a cortical lesion. Neither tone decay nor Békésy shifts were present. One could speculate whether Tone Decay/Békésy results might be significant with cortical lesion were these tests also made more difficult, for example, by adopting a two- or three-minute, *rather than* a one minute, criterion for tone decay

Discussion

Comments on ABLB

Of major concern is that the special tests pointed to cochlear involvement in 22% of patients with known retrocochlear lesion. This percentage is in contrast to the 10 reported by Dix & Hallpike (1960) for the ABLB test alone and the approximately 40% reported by Johnson (1968) for a test battery similar to that of the present survey Johnson's data indicated that a substantial proportion of the patients in this 40% showed inter-test inconsistencies, which might have been interpreted as suggestive of retrocochlear involvement in light of the inter-test consistency of the cochlear lesion patients in the present survey and the consistency on ABLB shown by patients with Meniere's disease reported by Hood (1969).

No doubt the differences in results for the three studies are at least in part a function of the populations involved. Johnson felt that the less positive auditory findings for his 1968 series compared to an earlier series "may be partially explained on the basis of earlier detection of acoustic neuroma before the cochlear branch of the eighth nerve is fully involved" With respect to Hood's population, the cochlear group consisted entirely of patients with Menière's disease, a relatively clear-cut cochlear entity Slightly greater uncertainty regarding site of lesion may be encountered in patients with other kinds of cochlear impairment and in some patients with a history of sudden loss.

Hood (1969) in his work with Dix & Hallpike, placed reliance primarily on the *ABLB* test in *differentiating* between cochlear and retrocochlear lesions. If we had depended only upon the ABLB *test*, however we would have failed to disclose audiometric evidence of retrocochlear involvement not only in the 17 pa-

tients for whom all special test results indicated cochlear involvement, but in four others for whom ABLB indicated cochlear involvement while Tone Decay/Békésy indicated retrocochlear involvement. Also valid ABLB testing was precluded in six of our 78 patients with retrocochlear lesion in whom retrocochlear involvement was indicated by the Tone Decay and Békésy tests. Three of the six had normal and equal pure tone thresholds bilaterally one had a bilateral high-tone loss another was a seven-year-old child who could not perform reliably on the ABLB and the sixth had a reversal in pure-tone thresholds—that is the ear affected by the tumor showed better thresholds than the opposite ear which had been affected primarily by exposure to noise. If to these six patients we add the 21 above we would have failed to disclose audiometric evidence of retrocochlear involvement in 27 instances (35%) with only ABLB Also we found a few patients who experienced much difficulty in the loudness balancing task and a few others whose severe losses precluded completion of the ABLB (The SISI test often served nicely in these instances) Clearly either the Tone Decay or Békésy test is necessary for a thorough investigation of possible retrocochlear involvement. In fact, if the audiologist were limited to one test, he would be wiser to select the Tone Decay or Békésy (fixed frequency) because either can be used with validity for all but the most severe losses Of these two tests the Békésy would probably be the better choice because the Tone Decay test seems slightly more prone to artifact. Using Tone Decay/Békésy alone, we would have failed to disclose retrocochlear involvement in 20 patients (26%) of the Retrocochlear Lesion group—that is in the 17 exceptional patients mentioned earlier plus three others who showed neither recruitment nor significant Tone Decay/Békésy results.

Hood would no doubt suggest that ABLB should have been done to explore for possible "loudness reversal"[1] in four of the six patients mentioned above namely the three with normal and equal hearing for pure tones bilaterally and the one with a bilateral high-tone loss. ABLB was done in only one of the three patients with normal and equal pure tone hearing bilaterally and no abnormality of loudness growth was found. The importance of ABLB in such cases is not denied but loudness reversal will not be found in all instances. Should loudness reversal (decruitment) be demonstrated, however information from Tone Decay/Békésy would still be needed. For example abnormally slow loudness growth has been shown in the ear contralateral to a cortical lesion (Jerger 1960 b Davis & Goodman, 1966 Hodgson, 1967) but in such a lesion the affected ear has shown no significant Békésy shifts (Goetzinger & Angell 1965 Hodgson 1967) Thus the occurrence of Type III tone decay or significant Békésy shifts on the same side as the loudness reversal might suggest a retrocochlear lesion lower in the auditory system as opposed to cortical involvement.

The marked discrepancy between Hood's (1969) and our results for ABLB called for a review of our findings Except for our portraying the loudness matches on laddergrams instead of graphs, our ABLB procedure for 70% of the patients (those in whom the reference tones for the loudness matches were fixed in the better ear) was not unlike the one described by Hood in 1969 His comments, however were directed to the Jerger (1962) method of fixing the reference tone in the poorer ear which method we followed in 30% of our patints Hood was concerned that Jerger's method might tend to *hide* recruitment where it is actually present thus suggesting a retrocochlear lesion that does not exist. It is interesting that our problem was the reverse. recruitment often camouflaged an existing retrocochlear lesion It should be stressed that in the patients for whom the reference tone was

[1] Hood and his co-workers have employed the term loudness reversal" for the abnormally slow growth of loudness in the affected ear More recently Davis & Goodman (1966) have employed the term decruitment for the same phenomenon.

fixed in the poorer ear our approach was a manual one that did not follow the complete protocol offered by Jerger (1962)

For the *Menière's Disease + Other Cochlear Lesion group* 80 laddergrams were carried to completion "fixing" the better ear at 20 dB intervals. Recruitment was complete in 74 patients, and partial, but clearly present, in six. In 29 other patients fixing the better ear the laddergram was not completed because recruitment was immediately evident after two or three matches, or recruitment was reported in the records, but the laddergrams were not available for analysis.

In 48 patients from the *Menière's Disease + Other Cochlear Lesion* group, the reference tone was fixed in the poorer ear Following Jerger's (1962) definitions, recruitment was found to be complete in 33 and partial in 15 patients.

In the *Retrocochlear Lesion* group, excluding the 17 exceptional patients mentioned earlier 24 laddergrams fixing the better ear were carried to completion. 23 showed no evidence of recruitment and one showed complete recruitment at the only testable frequency (4 000 Hz). The affected ear was fixed in 18 patients. 14 showed no evidence of recruitment, three showed partial recruitment at one frequency and no recruitment at other frequencies and one showed partial recruitment at several frequencies.

For the 17 *Retrocochlear Lesion* patients whose special test results indicated cochlear involvement, laddergrams fixing the better ear were carried to completion in nine: eight showed complete recruitment, and one showed partial recruitment In a tenth patient, the laddergram was not completed because recruitment was immediately obvious. In four other patients, the poorer ear was fixed. complete recruitment was shown in one, partial recruitment in three. For the remaining three of the 17 patients, ABLB testing was not feasible in one and was omitted in the other two (in these two, SISI scores were 100 %) In retrospect, ABLB results for two of the 17 patients were of special interest. Both showed recruitment at one testable frequency but not at others. These results occurred in three of the *Retrocochlear Lesion* group for whom retrocochlear lesion was indicated on the basis of Tone Decay/ Békésy results, but in none of the *Menière's Disease* group and in only two of the *Other Cochlear Lesion group*. Consequently such results should strongly suggest the possibility of retrocochlear lesion. Obviously if feasible ABLB testing should be done for at least two frequencies.

It was readily evident that a higher proportion of "partial" recruitment results occurred when the reference tone was fixed in the poorer ear probably in part because only one loudness match (at 20 dB SL) was obtained in the majority of cases. Although the ABLB results generally supported the common policy of associating partial recruitment with cochlear involvement, the fact that partial recruitment occurred occasionally in the *Retrocochlear Lesion* group suggests the advisability of carrying out the test until the whole picture of recruitment can be seen, regardless of which ear is fixed. Hood (1969) in this connection reported that in a series of 424 patients with Menière's disease, all showed recruitment, and in 415 the recruitment was complete. This left only 9 (2 %) showing partial recruitment. Partial recruitment, by itself should not be considered a strong indicator of cochlear involvement.

Since the data of this survey are insufficient to weigh adequately the merits of fixing the good versus the bad ear the matter will not be pursued. An appeal of the Hood approach to ABLB however lies in his report that even when loudness recruitment occurs with VIIIth nerve lesions, the majority of recruitment curves differ conspicuously from those for patients with Menière's disease. He maintains "that these small but clinically significant features can only be revealed if (*a*) a systematic series of balancing points is established at intervals of 20 dB in the good ear and (*b*) the results are graphically displayed and not transferred to ladder diagrams A pertinent question, of

course, is whether the recruitment curves of Menière's disease patients can be generalized to patients with other kinds of cochlear impairment.

In any event, we agree with Hood that the primary need is for careful testing by a skilled and resourceful audiologist In the population suspected of possible retrocochlear involvement the audiologist must often work against the patient's anxiety fatigue or illness, and must often obtain maximum information in a minimum of time. Testing time can be reduced in many instances For example, consider a patient with a history suggestive of Menière's disease, a closing" or "constricting" pure tone pattern and W 22 scores generally proportionate to the pure tone levels If complete loudness recruitment or high SISI scores are demonstrated at two or three frequencies, the testing can usually be concluded satisfactorily by a screening for tone decay or by a few fixed frequency Békésy tracings Similarly consider a patient with a vague history of onset the likelihood of progressive loss a widening" pure tone pattern and an extremely low W 22 score in the face of a mild pure-tone loss in the affected ear Significant fixed frequency Békésy shifts or Type III tone decay at a few frequencies should be sufficient to report evidence of retrocochlear involvement. An absence of recruitment, or low SISI scores would add strength to the evidence. In other words, completion of all four special tests in the above examples would typically yield no additional information clinically speaking, with regard to the question of cochlear versus retrocochlear involvement. Usually the need for further testing is indicated by the definitiveness and consistency of the first two special tests that are employed—for example, the ABLB and Tone Decay ABLB and Békésy SISI and Tone Decay or SISI and Békésy

Summary of Results

A survey was conducted on audiometric findings for a series of patients with sensorineural hearing loss, who had been referred for special audiologic tests on suspicion of retrocochlear lesion. The patients were classified into four groups *Menière's Disease Other Cochlear Lesion Retrocochlear Lesion* and *Sudden Loss* Findings were as follows

1 Bilateral pure-tone hearing loss with presumably the same kind of impairment in each ear was not an outstanding feature in any group It was highest in the *Menière's Disease* and *Other Cochlear Lesion* groups (16% and 12%) less common in the *Sudden Loss* group (4%) and rare in the *Retrocochlear Lesion* group occurring only in a patient with von Recklinghausen's disease.

2. Total unilateral pure tone loss was found primarily in the *Sudden Loss* and *Retrocochlear Lesion* groups, rarely in the *Menière's Disease* and *Other Cochlear Lesion* groups.

3 Pure-tone patterns for unilateral loss patients were classified according to the relation between the configurations for the two ears, thus taking into consideration the prevalence of better-ear high-tone loss in all groups. Parallel" patterns were found in all groups, but relatively less often in the *Retrocochlear Lesion* group Constricting" patterns occurred almost exclusively in the *Menière's Disease* and *Other Cochlear Lesion* groups. Closing" patterns predominated in the *Menière's Disease* and *Other Cochlear Lesion* groups they occurred frequently in the *Sudden Loss* group although only with greater degrees of impairment, and they were infrequent in the *Retrocochlear Lesion* group. Widening" patterns were characteristic of the *Retrocochlear Lesion* group, but they

also occurred frequently in the *Sudden Loss* group they were relatively infrequent in the *Menière's Disease* and *Other Cochlear Lesion* groups. "Closing both ends" patterns were infrequent and occurred only in the *Other Cochlear Lesion* and *Retrocochlear Lesion* groups. The possibility of retrocochlear involvement is thus suggested by "widening" patterns in the absence of sudden loss, and by "closing both ends" patterns the possibility of retrocochlear involvement is also suggested by "parallel" patterns with a minimal pure-tone difference (10–25 dB) between the two ears. Cochlear involvement in the form of hydrops is suggested by "closing" patterns in the absence of sudden loss and by "constricting" patterns.

4. When discrimination scores on the W 22 lists fell below 48% with thresholds of less than 40 dB for the Fletcherian pure-tone average, retrocochlear involvement could be predicted with high confidence. The only exceptions were in elderly patients or patients with a sharply downward sloping pure-tone configuration in the speech frequency range. Depending upon the pure-tone hearing level, scores both lower and higher than 48% offered clues in predicting retrocochlear lesion.

5. Special tests (ABLB, SISI, Tone Decay and Békésy) were given to 170 of the *Menière's Disease* group, 62 of the *Other Cochlear Lesion* group 78 of the *Retrocochlear Lesion* group, and 73 of the *Sudden Loss* group. Evidence suggested that when two tests—one of each pair (*ABLB SISI* and *Tone Decay Békésy*)—provided definitive results, further testing typically added no information with respect to cochlear versus retrocochlear lesion. In the *Menière's Disease* and *Other Cochlear Lesion* groups combined, four patients, two in each group showed mixed cochlear-retrocochlear signs. The remaining 178 patients (97.8%) with cochlear lesions showed cochlear signs. In the *Retrocochlear Lesion* group, 53 patients (68) showed retrocochlear signs, 17 (%) showed cochlear signs, and eight (10%) showed mixed cochlear retrocochlear signs. In the *Sudden Loss* group, 55 patients (75%) showed cochlear signs, ten (14%) showed retrocochlear signs, and eight (11%) showed mixed cochlear-retrocochlear signs.

Accordingly in the absence of a history of sudden loss, mixed cochlear-retrocochlear signs suggest the likelihood of retrocochlear involvement. These mixed signs usually refer to discrepancies between the two pairs of tests—ABLB/SISI versus Tone Decay/Békésy—regarding site of lesion, and emphasize the importance of doing at least one of the tests in each pair preferably at the same three or four frequencies.

6. The special test findings for two small groups of patients with normal or near-normal pure tone thresholds stressed the importance of bilateral testing for at least Tone Decay or Békésy shifts when patients are referred on suspicion of retrocochlear involvement. These findings also demonstrated that fixed-frequency Békésy tracings were generally more sensitive to retrocochlear involvement than sweep tracings.

7. Inconsistent, unusual, or otherwise suspicious test results regarding site of lesion can often be resolved upon retesting after a few months. The following are apt to occur with retrocochlear involvement. (*a*) an increase in pure-tone hearing loss (although there seems no lawful pattern of progression with respect to the frequency range affected) (*b*) a reduction in speech discrimination that is sometimes markedly out of proportion to pure-tone changes and (*c*) changes in special test results with respect to site of lesion.

8. Observation of the constellations of test results suggested the following: (*a*) Retrocochlear involvement should be reported as a possibility with "widening" or "closing both ends" pure-tone patterns, even when they appear with cochlear special test findings, and especially when the history of onset is vague. (*b*) Cochlear involvement, and the absence of retrocochlear involvement, can be predicted with a high degree of confidence for a given individual

course, is whether the recruitment curves of Menière's disease patients can be generalized to patients with other kinds of cochlear impairment.

In any event, we agree with Hood that the primary need is for careful testing by a skilled and resourceful audiologist. In the population suspected of possible retrocochlear involvement, the audiologist must often work against the patient's anxiety fatigue, or illness, and must often obtain maximum information in a minimum of time. Testing time can be reduced in many instances For example, consider a patient with a history suggestive of Menière's disease, a "closing" or "constricting" pure tone pattern, and W 22 scores generally proportionate to the pure-tone levels If complete loudness recruitment or high SISI scores are demonstrated at two or three frequencies, the testing can usually be concluded satisfactorily by a screening for tone decay or by a few fixed frequency Békésy tracings. Similarly consider a patient with a vague history of onset, the likelihood of progressive loss, a "widening" pure tone pattern, and an extremely low W 22 score in the face of a mild pure tone loss in the affected ear Significant fixed frequency Békésy shifts or Type III tone decay at a few frequencies should be sufficient to report evidence of retrocochlear involvement. An absence of recruitment or low SISI scores, would add strength to the evidence. In other words, completion of all four special tests in the above examples would typically yield no additional information clinically speaking, with regard to the question of cochlear versus retrocochlear involvement. Usually the need for further testing is indicated by the definitiveness and consistency of the first two special tests that are employed—for example the ABLB and Tone Decay ABLB and Békésy SISI and Tone Decay or SISI and Békésy

Summary of Results

A survey was conducted on audiometric findings for a series of patients with sensorineural hearing loss, who had been referred for special audiologic tests on suspicion of retrocochlear lesion The patients were classified into four groups. *Menière's Disease Other Cochlear Lesion Retrocochlear Lesion* and *Sudden Loss* Findings were as follows

1 Bilateral pure-tone hearing loss with presumably the same kind of impairment in each ear was not an outstanding feature in any group It was highest in the *Menière's Disease* and *Other Cochlear Lesion* groups (16% and 12%) less common in the *Sudden Loss* group (4%) and rare in the *Retrocochlear Lesion* group occurring only in a patient with von Recklinghausen's disease

2. Total unilateral pure tone loss was found primarily in the *Sudden Loss* and *Retrocochlear Lesion* groups rarely in the *Menière's Disease* and *Other Cochlear Lesion* groups

3 Pure-tone patterns for unilateral loss patients were classified according to the relation between the configurations for the two ears, thus taking into consideration the prevalence of better-ear high-tone loss in all groups. "Parallel" patterns were found in all groups, but relatively less often in the *Retrocochlear Lesion* group. "Constricting" patterns occurred almost exclusively in the *Menière's Disease* and *Other Cochlear Lesion groups* "Closing" patterns predominated in the *Menière's Disease* and *Other Cochlear Lesion* groups they occurred frequently in the *Sudden Loss* group although only with greater degrees of impairment, and they were infrequent in the *Retrocochlear Lesion* group. "Widening" patterns were characteristic of the *Retrocochlear Lesion* group, but they

also occurred frequently in the *Sudden Loss* group, they were relatively infrequent in the *Menière's Disease* and *Other Cochlear Lesion* groups. "Closing both ends" patterns were infrequent and occurred only in the *Other Cochlear Lesion* and *Retrocochlear Lesion* groups. The possibility of retrocochlear involvement is thus suggested by "widening" patterns in the absence of sudden loss, and by "closing both ends" patterns the possibility of retrocochlear involvement is also suggested by "parallel" patterns with a minimal pure-tone difference (10-25 dB) between the two ears. Cochlear involvement in the form of hydrops is suggested by "closing" patterns in the absence of sudden loss and by "constricting" patterns.

4. When discrimination scores on the W-22 lists fell below 48% with thresholds of less than 40 dB for the Fletcherian pure-tone average, retrocochlear involvement could be predicted with high confidence. The only exceptions were in elderly patients or patients with a sharply downward sloping pure-tone configuration in the speech frequency range. Depending upon the pure-tone hearing level, scores both lower and higher than 48% offered clues in predicting retrocochlear lesion.

5. Special tests (ABLB, SISI, Tone Decay and Békésy) were given to 120 of the *Menière's Disease* group, 62 of the *Other Cochlear Lesion* group, 78 of the *Retrocochlear Lesion* group, and 73 of the *Sudden Loss* group. Evidence suggested that when two tests—one of each pair (ABLB/SISI and Tone Decay/Békésy)—provided definitive results, further testing typically added no information with respect to cochlear versus retrocochlear lesion. In the *Menière's Disease* and *Other Cochlear Lesion* groups combined, four patients, two in each group, showed mixed cochlear-retrocochlear signs. The remaining 178 patients (97.8%) with cochlear lesions showed cochlear signs. In the *Retrocochlear Lesion* group, 53 patients (68) showed retrocochlear signs, 17 (22%) showed cochlear signs, and eight (10%) showed mixed cochlear-retrocochlear signs. In the *Sudden Loss* group, 55 patients (75%) showed cochlear signs, ten (14%) showed retrocochlear signs, and eight (11%) showed mixed cochlear-retrocochlear signs.

Accordingly, in the absence of a history of sudden loss, mixed cochlear-retrocochlear signs suggest the likelihood of retrocochlear involvement. These mixed signs usually refer to discrepancies between the two pairs of tests—ABLB/SISI versus Tone Decay/Békésy—regarding site of lesion, and emphasize the importance of doing at least one of the tests in each pair, preferably at the same three or four frequencies.

6. The special test findings for two small groups of patients with normal or near-normal pure-tone thresholds stressed the importance of bilateral testing for at least Tone Decay or Békésy shifts when patients are referred on suspicion of retrocochlear involvement. These findings also demonstrated that fixed-frequency Békésy tracings were generally more sensitive to retrocochlear involvement than sweep tracings.

7. Inconsistent, unusual, or otherwise suspicious test results regarding site of lesion can often be resolved upon retesting after a few months. The following are apt to occur with retrocochlear involvement: (*a*) an increase in pure-tone hearing loss (although there seems no lawful pattern of progression with respect to the frequency range affected), (*b*) a reduction in speech discrimination that is sometimes markedly out of proportion to pure-tone changes, and (*c*) changes in special test results with respect to site of lesion.

8. Observation of the constellations of test results suggested the following: (*a*) Retrocochlear involvement should be reported as a possibility with "widening" or "closing both ends" pure-tone patterns, even when they appear with cochlear special test findings, and especially when the history of onset is vague. (*b*) Cochlear involvement, and the absence of retrocochlear involvement, can be predicted with a high degree of confidence for a given individual

course, is whether the recruitment curves of Menière's disease patients can be generalized to patients with other kinds of cochlear impairment.

In any event, we agree with Hood that the primary need is for careful testing by a skilled and resourceful audiologist. In the population suspected of possible retrocochlear involvement, the audiologist must often work against the patient's anxiety, fatigue or illness, and must often obtain maximum information in a minimum of time. Testing time can be reduced in many instances. For example consider a patient with a history suggestive of Menière's disease, a "closing" or "constricting" pure tone pattern and W 22 scores generally proportionate to the pure tone levels. If complete loudness recruitment or high SISI scores are demonstrated at two or three frequencies, the testing can usually be concluded satisfactorily by a screening for tone decay or by a few fixed frequency Békésy tracings. Similarly consider a patient with a vague history of onset, the likelihood of progressive loss, a "widening" pure tone pattern and an extremely low W 22 score in the face of a mild pure tone loss in the affected ear. Significant fixed-frequency Békésy shifts or Type III tone decay at a few frequencies should be sufficient to report evidence of retrocochlear involvement. An absence of recruitment or low SISI scores, would add strength to the evidence. In other words, completion of all four special tests in the above examples would typically yield no additional information, clinically speaking, with regard to the question of cochlear versus retrocochlear involvement. Usually the need for further testing is indicated by the definitiveness and consistency of the first two special tests that are employed—for example, the ABLB and Tone Decay, ABLB and Békésy, SISI and Tone Decay, or SISI and Békésy.

Summary of Results

A survey was conducted on audiometric findings for a series of patients with sensorineural hearing loss, who had been referred for special audiologic tests on suspicion of retrocochlear lesion. The patients were classified into four groups: *Menière's Disease*, *Other Cochlear Lesion*, *Retrocochlear Lesion* and *Sudden Loss*. Findings were as follows.

1. Bilateral pure tone hearing loss with presumably the same kind of impairment in each ear was not an outstanding feature in any group. It was highest in the *Menière's Disease* and *Other Cochlear Lesion* groups (16% and 12%), less common in the *Sudden Loss* group (4%) and rare in the *Retrocochlear Lesion* group, occurring only in a patient with von Recklinghausen's disease.

2. Total unilateral pure tone loss was found primarily in the *Sudden Loss* and *Retrocochlear Lesion* groups, rarely in the *Menière's Disease* and *Other Cochlear Lesion* groups.

3. Pure-tone patterns for unilateral loss patients were classified according to the relation between the configurations for the two ears, thus taking into consideration the prevalence of better-ear high-tone loss in all groups. "Parallel" patterns were found in all groups, but relatively less often in the *Retrocochlear Lesion* group. "Constricting" patterns occurred almost exclusively in the *Menière's Disease* and *Other Cochlear Lesion* groups. "Closing" patterns predominated in the *Menière's Disease* and *Other Cochlear Lesion* groups; they occurred frequently in the *Sudden Loss* group although only with greater degrees of impairment, and they were infrequent in the *Retrocochlear Lesion* group. "Widening" patterns were characteristic of the *Retrocochlear Lesion* group, but they

also occurred frequently in the *Sudden Loss* group; they were relatively infrequent in the *Menière's Disease* and *Other Cochlear Lesion* groups. "Closing both ends" patterns were infrequent and occurred only in the *Other Cochlear Lesion* and *Retrocochlear Lesion* groups. The possibility of retrocochlear involvement is thus suggested by "widening" patterns in the absence of sudden loss, and by "closing both ends" patterns, the possibility of retrocochlear involvement is also suggested by "parallel" patterns with a minimal pure-tone difference (10–25 dB) between the two ears. Cochlear involvement in the form of hydrops is suggested by "closing" patterns in the absence of sudden loss and by "constricting" patterns.

4. When discrimination scores on the W-22 lists fell below 48% with thresholds of less than 40 dB for the Fletcherian pure-tone average, retrocochlear involvement could be predicted with high confidence. The only exceptions were in elderly patients or patients with a sharply downward sloping pure-tone configuration in the speech frequency range. Depending upon the pure-tone hearing level, scores both lower and higher than 48% offered clues in predicting retrocochlear lesion.

5. Special tests (ABLB, SISI, Tone Decay and Békésy) were given to 120 of the *Menière's Disease* group, 62 of the *Other Cochlear Lesion* group, 78 of the *Retrocochlear Lesion* group, and 73 of the *Sudden Loss* group. Evidence suggested that when two tests—one of each pair (ABLB/SISI and Tone Decay/Békésy)—provided definitive results, further testing typically added no information with respect to cochlear versus retrocochlear lesion. In the *Menière's Disease* and *Other Cochlear Lesion* groups combined, four patients, two in each group, showed mixed cochlear-retrocochlear signs. The remaining 178 patients (97.8%) with cochlear lesions showed cochlear signs. In the *Retrocochlear Lesion* group, 53 patients (68) showed retrocochlear signs, 17 (22%) showed cochlear signs, and eight (10%) showed mixed cochlear-retrocochlear signs. In the *Sudden Loss* group, 55 patients (75%) showed cochlear signs, ten (14%) showed retrocochlear signs, and eight (11%) showed mixed cochlear-retrocochlear signs.

Accordingly, in the absence of a history of sudden loss, mixed cochlear-retrocochlear signs suggest the likelihood of retrocochlear involvement. These mixed signs usually refer to discrepancies between the two pairs of tests—ABLB/SISI versus Tone Decay/Békésy—regarding site of lesion, and emphasize the importance of doing at least one of the tests in each pair, preferably at the same three or four frequencies.

6. The special test findings for two small groups of patients with normal or near normal pure-tone thresholds stressed the importance of bilateral testing for at least Tone Decay or Békésy shifts when patients are referred on suspicion of retrocochlear involvement. These findings also demonstrated that fixed-frequency Békésy tracings were generally more sensitive to retrocochlear involvement than sweep tracings.

7. Inconsistent, unusual, or otherwise suspicious test results regarding site of lesion can often be resolved upon retesting after a few months. The following are apt to occur with retrocochlear involvement: (*a*) an increase in pure-tone hearing loss (although there seems no lawful pattern of progression with respect to the frequency range affected); (*b*) a reduction in speech discrimination that is sometimes markedly out of proportion to pure-tone changes; and (*c*) changes in special test results with respect to site of lesion.

when cochlear special test results are combined with bilateral loss or with a "closing" or "constricting" pure-tone pattern (*c*) Brain-stem lesion as opposed to VIIIth-nerve lesion, is suggested when Type III tone decay patterns and/or significant Békésy *shifts (1) occur bilaterally* (2) occur unilaterally with normal or near normal pure tone hearing, or (3) occur with high discrimination scores 80% or higher on the W 22 lists The suggestion of brain stem lesion is probably strongest in (1) weakest in (3) (*d*) Meaningful correlations could not be *found* between particular test constellations and type or size of retrocochlear lesion.

Conclusions

For the group of patients described here, who were referred to the audiology clinic on suspicion of retrocochlear hearing impairment the following conclusions may be drawn

1 The ABLB SISI Tone Decay and Békésy hearing tests are invaluable adjuncts to the basic pure tone and speech reception tests. If certain discrepancies between the tests are included as indicators of retrocochlear involvement, such involvement should be correctly predicted in at least 78% of the cases.

2 On the other hand, the failure of all four tests to correctly predict approximately one out of five retrocochlear lesions (22%) indicates that caution is necessary in interpretation, and that other audiometric clues must be observed

3 The pure-tone findings are definitely helpful in predicting retrocochlear lesion and may serve to reduce the failure rate of the special tests.

4 Extremely low speech-discrimination scores may provide a strong indication of retrocochlear involvement, especially in cases where pure tone impairment is relatively mild

5 Because of the general consistency and definitiveness of the four special tests in the patients with cochlear lesion, the occurrence of any unusual or inconsistent findings should alert the audiologist to the possibility of retrocochlear involvement. In such cases, retesting at a later date often produces definitive information.

6 Limitations and possible artifacts are present in all four special tests, and one or more may fail to provide reliable and valid results for a given patient. Assuming good reliability however the ABLB and the SISI tests typically point to the same conclusion regarding cochlear versus retrocochlear lesion as do the Tone Decay and Békésy tests.

7 Certain constellations of test results including pure-tone findings and speech-discrimination scores may strengthen prediction of cochlear or retrocochlear involvement they may help in differentiating between VIIIth-nerve and brain-stem involvement and they may help in distinguishing between hydrops and other kinds of cochlear involvement. (Lesions of the higher auditory pathways and cortex were not included in this survey)

8 Accurate history of the onset of hearing impairment is important, because patients who experience sudden loss often show the same pure tone patterns, speech-discrimination results, and special test results as patients with retrocochlear lesions, although no lesions at least in the form of neoplasms, have been found in our *Sudden Loss* patients to date

UPPSALA 1971

Introduction

The experiments reported herein compare the effects of cooling, attenuation of test click, and physiological masking on the auditory-nerve action-potential response to clicks (abbreviated AP). By using averaged APs the effects of the three treatments on AP wave form could be compared much more confidently than is possible with photographs of single oscilloscope traces.

In this report, physiological masking is defined as the reduction in AP amplitude which is observed when white noise, or a pure tone of low-to-moderate intensity is applied along with the click (Coats, 1967). With physiological masking, the click microphonic is unchanged, and the term, as used in this report, excludes the effects of high-intensity stimuli where microphonic depression is observed.

Methods

Recording and data processing

APs were recorded from the round window and auditory nerve of the cat. A silver-ball electrode was used to record from the round window and a coaxial electrode was used to record from the auditory nerve. All of the results presented were confirmed with recordings from both locations.

Two different methods of data analysis were used. In earlier experiments, we photographed oscilloscope records of the click APs and took measurements from the photographs. More recently we recorded the APs on magnetic tape and averaged them off-line with a LINC-8 computer.

Fig. 1 shows a block diagram of the recording and data-processing system. The preparation was in an electrically shielded, sound-isolating room; the electrodes were led to a differential preamplifier (Tektronix, type 122), with the upper 3-dB point set at 10 kHz and the lower 3-dB point at 80 Hz.

The output of the preamplifier was led to one channel of an analog tape recorder (Precision Instruments) and was also monitored by an oscilloscope. The electrical square wave, which drove the earspeaker to produce the click stimulus, was recorded on a second tape channel and served as a trigger pulse to start analog-to-digital conversion. A third channel contained a "level code" (±1 V d.c.) which was used to signal the end of one run and the beginning of another. The level code and APs were recorded at 60 inches/sec in the FM mode, giving a frequency response (±3 dB) of 0–20 000 Hz; the trigger pulse was recorded in the direct mode, giving a frequency response (±3 dB) of 100–20 000 Hz. The analog signal was reproduced into the LINC-8 analog-to-digital converter at 7 $^1/_2$ inches/sec, thus multiplying the effective conversion rate by 8.

The computer processed the data in two steps: (1) analog-to-digital conversion, and (2) averaging. Utility programs included a plotting program and a program for editing digital-data tapes.

The analog signal was converted into 8-bit

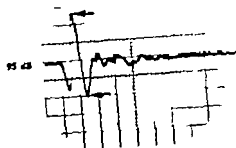
[Gen]eration of acoustic stimuli



[Fig]. 2 diagrams the instrumentation for gener[at]ing acoustic stimuli. Two electrically shielded [P]DR-600 earspeakers were mounted about 2 [cm] from the severed end of the external audi[to]ry canal. The masking stimuli were pro[du]ced by driving one of the earspeakers with the [o]utput of either a white-noise or a sine-wave [g]enerator. Driving the second earspeaker with [0].01 msec square-wave pulses produced the [c]licks. Decade attenuators calibrated in deci[b]els controlled sound intensity.

A weighted sound-intensity measurements were made with a probe-tube microphone which had been damped by packing with steel wool to make its frequency response as linear as possible. The probe tube was placed next to the severed end of the external canal (perpendicular incidence). The measurements were checked at the end of the experiment by removing the preparation and mounting a condenser microphone where the external canal had been.

All intensity measurements are expressed in sound-pressure level (dB re 0002 μbar). Click intensities are expressed in "peak-equivalent" dB, SPL. Fig. 3 shows the wave form of the click and the points used to determine peak to-peak amplitude. With the ear of a human observer placed approximately in the position occupied by the severed end of the animal's external canal, the click threshold was 25–30 dB peak-equivalent SPL. The "visual-detection level" of the *averaged* AP was generally about 5 dB below the human threshold. The visual-detection level of individual APs was at or slightly above human threshold.

Preparation of experimental animals

The cats were anesthetized with an intraperitoneal injection of Nembutal, and a d.c. heat lamp maintained body temperature during the experiment. A posterior approach to the bulla exposed the round window and, when nerve recordings were made, a dorsal approach (which included sucking out overlying cerebellum) ex-

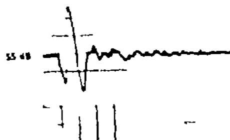


Fig. 3. Click stimuli at different intensities demonstrating linearity over the range studied. A 1-inch B & K condenser microphone (parallel incidence) located 2 inches from the speaker picked up the clicks. The frequency response of the sound level meter was linear over the 20–20 000 Hz range. Click intensities are given in peak-equivalent SPL. Arrows show the peaks used to determine peak-equivalent values. As we increased the click intensity we attenuated the input to the sound-level meter by an equal amount. Five superimposed traces are photographed. The time scale is 0.2 msec per division.

Preparation of experimental animals

The cats were anesthetized with an intraperitoneal injection of Nembutal, and a d.c. heat lamp maintained body temperature during the experiment. A posterior approach to the bulla exposed the round window and, when nerve recordings were made, a dorsal approach (which included sucking out overlying cerebellum) ex-

posed the auditory nerve All experiments, whether recordings were taken from nerve or round window were done with the bulla open. In all preparations the pinna was removed, leaving about a 3 mm stump of external canal.

In several experiments we cut the middle-ear muscles. Under microscopic observation the bony septum was removed with fine scissors and a rongeur A final widening of the opening was made with a dental drill, but we used the drill sparingly in order to avoid, insofar as possible acoustic trauma by bone-conducted sound

In all preparations with middle-ear muscles cut, we were careful to avoid accumulation of fluid in the middle-ear space All the reported results were obtained with middle-ear muscles cut and with them intact.

Application of localized temperature change

A thermoelectric cooling device, consisting of a bimetallic junction with one side equalized with running water and the other side thermally coupled to (but electrically insulated from) a silver rod 6 cm long, controlled the temperature in the vicinity of the cochlea. Teflon shink-fit" tubing insulated the rod, whose tip was bent upward about 30 and was flattened to provide a contact area of about 3 mm² Temperature at the tip of the rod was monitored with a calibrated thermocouple. A micromanipulator held the instrument and positioned it so that the flat tip of the rod rested firmly against the bony ledge beneath the round window

Results

Effects of masking, cooling and attenuation on AP latency and wave form

In five preparations AP amplitude was reduced equally by masking, cooling, and attenuation. All preparations were stimulated with 70–85 dB (peak equivalent) control clicks. Two were also stimulated with 60 dB control clicks. In each experiment, masking intensity and amount of cooling and attenuation were adjusted to produce about 50% reduction in N_1 amplitude

In Fig. 4 click APs equally reduced by attenuation, cooling, and masking are shown (plotter gain adjusted to produce equal amplitude so that wave forms can be compared) As illustrated by these records, cooling and attenuation always produced equal latency[1] increases, and the wave forms of the cooled and attenuated APs were nearly identical. (Small inconsistent differences in relative amplitudes of N_1 and N_2 were, however sometimes observed)

The records in Fig. 4 also demonstrate that, in comparison with cooling and attenuation, *masking has relatively little effect on* AP latency These records are, however atypical in that the slight latency increase usually observed with masking is not present. In this series, this was the only instance in which masking failed to produce a latency increase but a critical review of our earlier photographic records uncovered a few examples of either a failure to increase latency or a questionable latency increase. This apparent variability prompted the following additional study of the effect of masking on latency

[1] In all results reported here, "latency" refers to the interval between the electrical pulse producing the click and the peak of N_1 This includes sound-conduction time, which was about 60 μsec. Amplitude was measured from the first negative AP peak (N_1) to the positive peak between N_1 and N_2

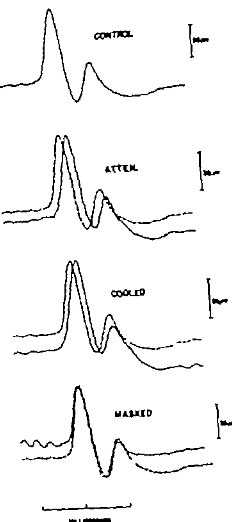

Fig. 4. Averaged click APs reduced equally by masking, cooling, and attenuation. As in all records shown in this report, upward deflection represents negativity at the round window. To facilitate waveform comparison, we adjusted the gain so that all tracings show equal N amplitude. The control click is retraced as dashed line onto the attenuated, cooled, and masked AP tracings. Each tracing is an average of 50 APs. The control-click intensity was 59 dB, peak equivalent SPL, and we attenuated the click by 9 dB to produce the second tracing. The cold probe, set at 12.5°C, produced the third tracing, and to produce the bottom tracing we applied white-noise masking stimulus of 30 dB, SPL.

Effect of intensity on latency change produced by masking

Plots of AP amplitude and latency versus click intensity (AP input–output curves) were obtained from four preparations. Also, in each preparation we set click intensity at two or three levels and masked with white noise at various intensities. In two preparations the middle-ear muscles were cut, and in the other two they were not cut. All four preparations yielded similar results.

Fig. 5 shows a click AP input–output curve, and Fig. 6 shows the effect of varying masking intensity. The masking-intensity scales are inverted to make the plots comparable to the input-output curve. It is apparent that the effect of masking on AP latency depends upon the relative intensities of masking and test-click stimuli. Over most of the masking and test-click intensity ranges, masking increases AP latency. However, when the test-click intensity is relatively low (e.g., the 50-dB click in Fig. 6) masking has an insignificant or barely significant effect on latency. At relatively high click intensities (e.g. the 70-dB click in Fig. 6), masking increases latency throughout the intensity range. At intermediate click intensities (e.g. the 60-dB click in Fig. 6), masking has a mixed effect on latency. As masking intensity increases from low levels, AP latency increases, and the latency increase is roughly proportional to the amplitude decrease. However, as masking intensity reaches a particular level (30–40 dB), latency again declines.

In all the previous instances in which masking appeared to have an insignificant effect on latency, click intensity was either low or moderate, and masking intensity was relatively high. Thus, the present results seem to identify the source of variability of the effect of masking on AP latency.

Throughout these experiments we consistently observed that masking, attenuation, and cooling not only increased the latency of the N peak, but also slightly broadened it. The effect

Effect of intensity on latency change produced by masking

Plots of AP amplitude and latency versus click intensity (AP input–output curves) were obtained from four preparations. Also, in each preparation we set click intensity at two or three levels and masked with white noise at various intensities. In two preparations the middle-ear muscles were cut, and in the other two they were not cut. All four preparations yielded similar results.

Fig. 5 shows a click AP input–output curve, and Fig. 6 shows the effect of varying masking intensity. The masking-intensity scales are inverted to make the plots comparable to the input–output curve. It is apparent that the effect of masking on AP latency depends upon the relative intensities of masking and test click stimuli. Over most of the masking and test-click intensity ranges, masking increases AP latency. However, when the test-click intensity is relatively low (e.g., the 50-dB click in Fig. 6), masking has an insignificant or barely significant effect on latency. At relatively high click intensities (e.g., the 70-dB click in Fig. 6), masking increases latency throughout the intensity range. At intermediate click intensities (e.g., the 60-dB click in Fig. 6), masking has a mixed effect on latency. As masking intensity increases from low levels, AP latency increases, and the latency increase is roughly proportional to the amplitude decrease. However, as masking intensity reaches a particular level (30–40 dB), latency again declines.

In all the previous instances in which masking appeared to have an insignificant effect on latency, click intensity was either low or moderate, and masking intensity was relatively high. Thus, the present results seem to identify the source of variability of the effect of masking on AP latency.

Throughout these experiments we consistently observed that masking, attenuation, and cooling not only increased the latency of the N_1 peak, but also slightly broadened it. The effect

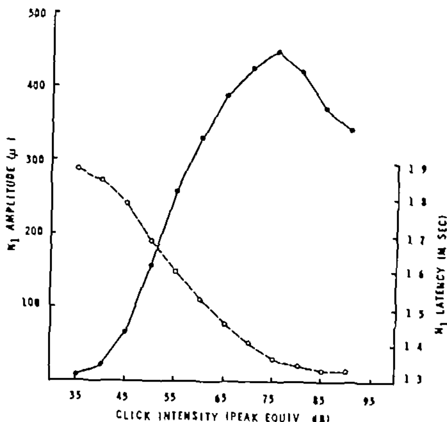

Fig 5 A latency (– –) and amplitude (——) plotted against click intensity

is small unless reduction in AP amplitude is quite large (at least 75%) Figs. 7 and 8 demonstrate this observation. The records shown in these figures were obtained by adjusting plotter gain to produce equal N_1 amplitudes and positioning so that the N_1 peaks coincide.

Effect of masking frequency on latency change produced by masking

Five preparations were masked with pure tones and three preparations with one-third-octave, band-passed white noise Each experiment tested frequencies ranging from 0 5 kHz to 12 kHz. Throughout each experiment the acoustic stimuli were monitored with a calibrated probe tube to be certain that there was no acoustic transducer overload at high intensities.

Masking at various frequencies produced no differential effects on masked AP latency This is illustrated by Figs. 9 and 10 Fig. 9 shows plots of masked amplitude and latency versus masking intensity for a series of masking frequencies (pure tones) These plots are equivalent to those in Fig. 6, except the latency scale has been expanded. It appears that for a given reduction in AP amplitude, masking produces the same latency increase regardless of masking frequency Fig. 10 shows this more directly In this figure, amplitude change (unmasked amplitude minus masked amplitude) is plotted against latency change (masked latency minus unmasked latency) The plots for different masking frequencies appear superimposable.

Latency change during onset of and recovery from masking

Four preparations were studied, two with the middle-ear muscles cut and two with them intact. In two preparations (one with and the other without middle-ear muscles cut) pure-tone and white noise masking yielded qualitatively similar results. The other preparations were masked only with white noise. We chose masking and test-click intensities to produce a maximal latency increase The rise-fall time of the masking stimulus was 7 5 msec Onset

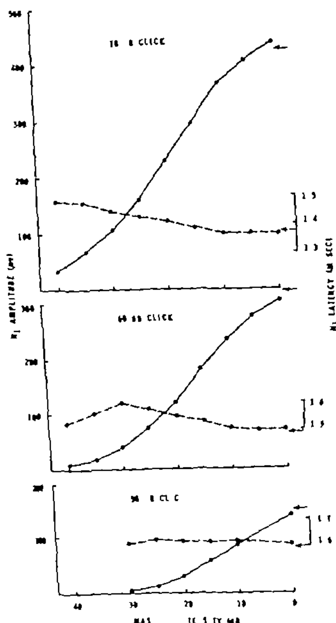

Fig. 6. N latency (– –) and amplitude (——) plotted against masking intensity (white noise) at three different test-click intensities. *This is the same preparation* show in Fig. 5 Arrows at the right show unmasked amplitudes. The masking-intensity scale has been inverted to facilitate comparison with the click AP input-output curve (Fig. 5).

and cutoff were smooth and reasonably free of echo (see Fig. 11). We obtained averaged responses to single clicks delivered at various times during and after cutoff and onset, and plotted onset and recovery curves for amplitude and latency

Typical results are shown in Figs. 12 and 13 For these figures, the latency scale is inverted to allow comparison of the latency and amplitude plots. As shown, latency follows amplitude *fairly closely* *both during the onset* and after the cutoff of the masking stimulus. The only possible exception is during the first few milliseconds of masking onset, where the latency increase appears to lag the decline in amplitude. This apparent dissociation appear

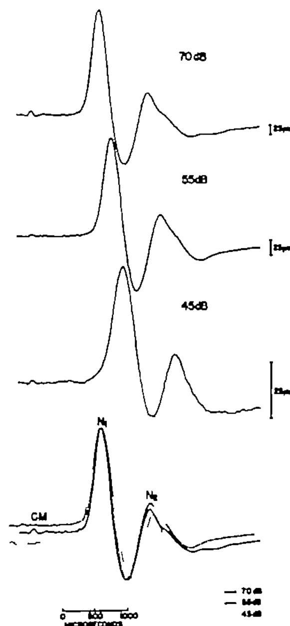

Fig 7 Effect of attenuation on the wave form of *N* Each tracing is an average of 70 responses (gain adjusted to produce equal *N* amplitude) Click intensity shown at the right, is in peak-equivalent decibels. At the bottom, the action potentials are retraced and positioned so that the *N* peaks coincide. The components of the round-window response are labeled *CM* – cochlear microphonic response to click. *N* = first negative whole-nerve AP peak. N = second negative AP peak. This is the same preparation shown in Figs. 5 and 6

ed in one of the other preparations but not in the remaining two We observed that at low masking intensities amplitude reduction is sometimes relatively greater than latency increase Therefore, this apparent dissociation between amplitude and latency during the first 2–3 msec of masking onset could be attributed to an intensity effect.

As a result of these experiments we conclude that there is no significant dissociation between either the time course of decline in AP amplitude and increase in latency at masking onset or the increase in AP amplitude and decrease in latency during recovery

Effect of temperature on masking recovery

We have previously reported that increasing masking duration does not change masked AP amplitude but does slow the recovery rate (Coats, 1964 *a*) In contrast, increasing masking intensity reduces masked amplitude but

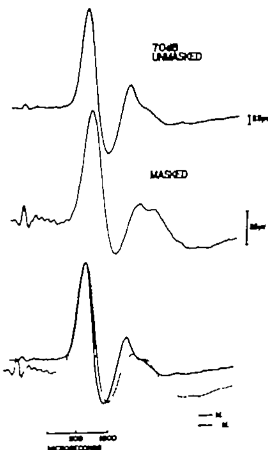

Fig 8 Effect of masking on the N wave form This is the same preparation shown in the preceding three figures. The middle-ear muscles were cut, and the masking stimulus was white noise at 38 dB SPL.

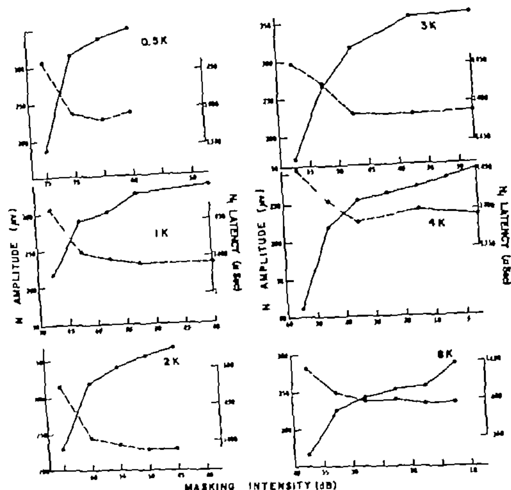

Fig. 9. N_1 latency (- -) and amplitude (——) plotted against masking intensity at six different masking frequencies (middle-ear muscles cut). Here, the masking stimuli were pure tones. Test-click intensity was 55 dB (peak equivalent). The *masking-intensity* scales have been inverted. Each data point was taken from an average of 30 round-window responses.

recovery from masking at different intensities (constant duration) follows a parallel time course (Coats, 1964 *b*). The effect of changing test-click intensity was equivalent to the effect of changing masking intensity. The experiments reported here were undertaken to determine whether the effect of temperature more closely resembles the effect of masking duration or of stimulus intensity.

Four preparations were masked with white noise. We cut the middle-ear muscles of two. Two preparations (one with and one without cut middle-ear muscles) were masked with a 500-Hz tone as well as with white noise. We applied each masking stimulus several times, and after each cutoff delivered a train of clicks (click rate = 20/sec). To plot recovery, we averaged every first AP, every second AP, and so forth.

The results, illustrated by Figs. 14 through 17, were essentially the same for all experiments. As shown in Figs. 14 and 15, when recovering AP amplitude is plotted as a percentage of unmasked (control) amplitude, the recovery curves appear roughly parallel, except that when recovery amplitude reaches 85–90 % of control amplitude, the curves begin to converge. Also, the recovery curve for the −5

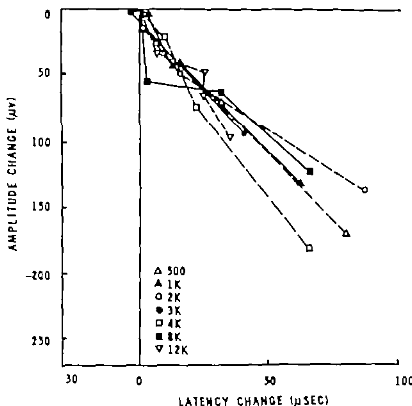

Fig 10 Latency change plotted against amplitude change at different masking frequencies. The data are the same as those plotted in Fig. 9

temperature at the long' masking duration seems to deviate slightly from the parallel course of the other curves

In studying the effects of varying test-click intensity we found that when test-click amplitude is varied the method of plotting recovery (i.e whether as a percentage of control or in absolute terms) has an effect on the apparent time course (Coats, 1967) Since changing temperature changes control amplitude, this effect also occurs with cooling Figs 16 and 17 show a replot of the recovery curves in Figs. 14 and 15 in terms of the difference between recovering and control amplitudes. These plots bear a striking resemblance to similar plots of recovery from masking at different test-click intensities (Coats, 1967) At relatively low control amplitudes (at low test-click intensities or at low temperatures) masking reduces AP amplitude less (in absolute terms) than at higher control amplitudes. As control amplitude increases (by increasing either temperature or click intensity) the difference between masked and unmasked AP amplitudes reaches a constant ("plateau") level. However regardless of control amplitude the time required for complete recovery remains constant. The experimental results thus lead to the conclusion that temperature affects masking in a way which resembles the effects of changing masking or test-click intensity rather than masking duration

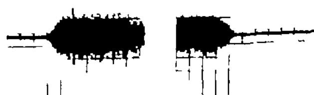

Fig 11 Condenser microphone record of onset and cutoff of the white-noise masking stimulus used to obtain the plots shown in Figs. 1 and 13 One horizontal division = 5 msec. Rise-fall time was 7 5 msec. Sound intensity was 50 dB, SPL. Each record is 10 superimposed oscilloscope traces.

The effects of masking cooling and attenuation on click-pair recovery

By measuring the amplitude of the second AP response at various interclick intervals, a click

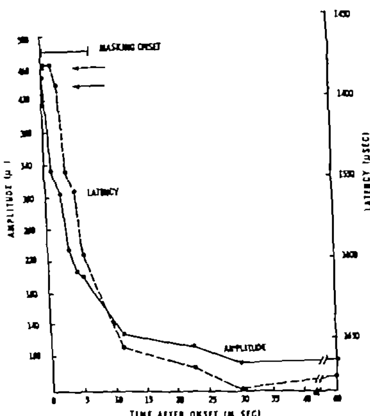

Fig 12 Time course of amplitude decline and latency increase at the onset of white-noise masking. The latency scale is inverted to facilitate comparison. Arrows at the left show unmasked values. Each data point was measured from an average of 25 round-window responses. Masking rise-fall time was 7.5 msec. Click intensity was 75 dB, peak-equivalent SPL.

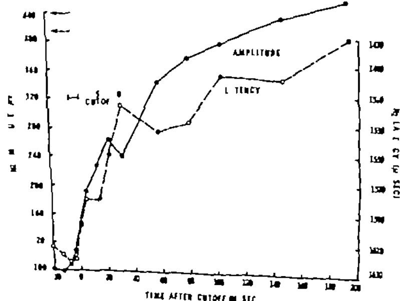

Fig 13 Time course of amplitude and latency recovery during and after cutoff of the same white-noise masking stimulus which produced the plots shown in Fig. 12 (the latency scale has been inverted). The time scale is compressed in comparison with the time scale in Fig. 12. The masking stimulus lasted 0.5 sec.

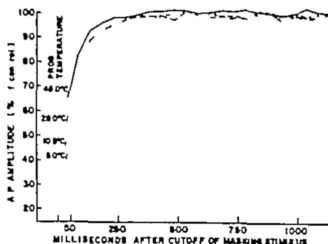

Fig 14 Click AP amplitude recovery following short duration (0 1. sec) masking at different temperatures. Temperature was controlled with a thermoelectric cold probe. The masking stimulus was a 65-dB, 2.5-kHz tone with a 7.5 msec rise–fall. Click intensity was 65 dB peak-equivalent SPL.

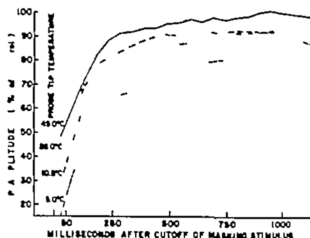

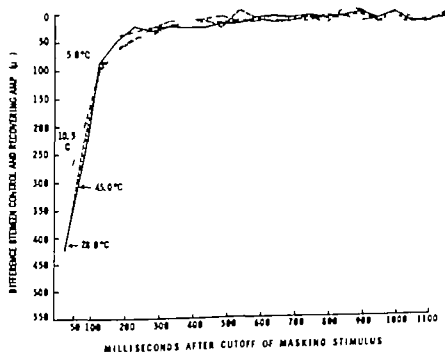

Fig 15 Click AP amplitude recovery following long duration (.4 sec) masking. All other parameters are the same as listed in the caption for Fig. 14.

pair recovery curve" can be plotted (Sørensen 1959 Dewson 1967) We have obtained additional information on the differential effects of masking, cooling, and attenuation from a series of experiments in which click pair recovery was compared under the three conditions

In each experiment, we obtained a control" click pair recovery curve using clicks of moderate intensity Masking, cooling, and attenuation reduced the control AP amplitude by about 50% with the parameters of each chosen to produce equal AP reduction Each of the three conditions yielded a click pair recovery curve which we compared with the control curve.

Fig. 18 illustrates typical results. Masked click pair recovery curves always reached con

F g 16 Click AP amplitude recovery at different temperatures following short-duration (0 12 sec) masking. These are the same curves as shown in Fig. 14 except that recovering AP amplitude is plotted in terms of difference between control (unmasked) and recovering amplitudes rather than as a percentage of control amplitude.

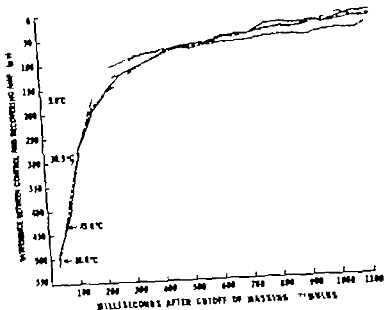

Fig. 17. Click AP amplitude recovery at different temperatures following long-duration (2.4 sec) masking. These are the same curves as shown in Fig. 15 except the recovering AP amplitude is plotted in terms of difference between control and recovering amplitudes rather than as a percentage of control amplitude.

trol values before control, attenuated, and cooled recovery curves. The attenuated and cooled recovery curves were always superimposable. The relationship between the attenuated and cooled recovery curves and the control recovery curve showed some variability. In three of eight experiments, the attenuated and cooled curves were superimposable on the control curves. In one experiment, attenuation and cooling seemed to slightly increase recovery rate. In the remaining four experiments, attenuation and cooling slowed recovery (see Fig. 18). In the four experiments in which cooling and attenuation failed to slow recovery, the intensity of the control click was at the lower end of the range used. It therefore seems possible that this variability is due to variation in control-click intensity.

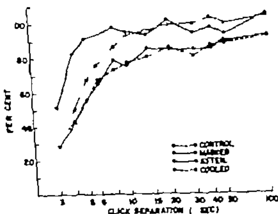

Fig. 18. Click-pair recovery curves with APs attenuated, cooled, and masked. The control-click intensity was 50 dB, peak-equivalent SPL, and the attenuated-click intensity was 35 dB, peak-equivalent SPL. We masked the clicks with white noise of 20 dB, SPL, and cooled with the probe-tip temperature at 10.0°C. The curves were obtained by measuring averages of 20 APs.

Discussion

In this attempt to interpret the above results, the following assumptions are implicit (1) The whole-nerve AP amplitude is determined by the number of fibers firing synchronously in response to the click. Alterations in AP amplitude are produced by changing the number of synchronously firing fibers (2) The AP peak latency is determined by the modal latency of the single fiber responses.

Effects of cooling and attenuation

In a previous report (Coats, 1965) we speculated that the quantitatively equal effects of cooling and attenuation on AP latency were due to the two treatments having a common mechanism of action We further suggested that cooling and attenuation slow the rise time (hence increasing AP latency) and reduce the amplitude (hence decreasing AP amplitude) of a hypothetical cochlear excitatory process. Since the change in microphonic amplitude caused by cooling and attenuation differed by an order of magnitude, this hypothetical excitatory process must be central to the microphonic generator

The present results establish that temperature and stimulus intensity have qualitatively similar effects on masking recovery and quantitatively equal effects on click pair recovery This enlarged list of similarities between temperature and stimulus intensity further supports the thesis that the two treatments act via a common mechanism.

The broadening of the *N* peak which occurs with cooling and attenuation is easily compatible with this hypothesis, since it could be attributed to the well known increased variability of single fiber response latency which occurs near threshold

Our data do not rule out the possibility that temperature affects the click AP by direct action on the nerve fibers rather than on the process which excites the nerve fibers. However if we assume a direct temperature effect on the auditory-nerve fibers, it becomes difficult to explain the similarities between cooling and attenuation, since attenuation would not be expected to change spike height or threshold of individual nerve fibers.

Effect of masking

The slight latency increase accompanying masking could be explained by assuming that a traveling wave, which begins at the basilar end of the cochlear partition and moves apically generates the click AP and by also assuming that the masking stimulus selectively removes the responses of basilar fibers. However this explanation is considered unlikely because the present investigation shows no differential masking-frequency effect on AP latency

It seems probable that in the present investigation we are dealing with a patch of sensory epithelium and its associated afferent nerve fibers which respond more or less equally to all stimulus frequencies (Tasaki & Fernández, 1952 Kiang et al. 1963) The results must therefore be explained on the basis of the neurophysiological properties of this system rather than its mechanical properties.

One way to explain the latency increase produced by masking is to assume that two mechanisms are operative—one the classical line busy mechanism the other depression of the hypothetical "presynaptic" cochlear excitatory process (Coats, 1964 *a*) The line-busy mechanism would not be expected to increase latency and could therefore be invoked to account for most of the AP reduction produced by masking. Depressing the presynaptic process could then be regarded as a secondary effect, which would account for the slight latency increase having the same qualitative properties as the latency increase produced by cooling and attenuation. Recovery of the excitatory process would also explain why recovery from masking is much slower than would be expected if only the line-busy mechanism were operative

Latency change at onset and after cutoff of masking is, however, not compatible with a "dual-mechanism" explanation of physiological masking. Implicit in the dual-mechanism hypothesis is the assumption that line-busy depression would recover much more rapidly than excitatory-process depression. Hence, we would expect that the early "rapid" recovery phase would be dominated by line-busy depression. Therefore, during the early phase, latency recovery should markedly lag amplitude recovery. In actuality we found no differential effects on latency during the early and late phases of masking recovery.

A third argument against this hypothesis is that it makes the increased rate of masked click-pair recovery difficult to explain. Since the second of a pair of click APs remains depressed about 50 msec, we would assume that the time course of click-pair recovery is almost solely accounted for by excitatory-process recovery. But, according to the dual-mechanism hypothesis, the masking stimulus should remove units almost entirely by the (postsynaptic) line-busy mechanism, and this would not be expected to alter the recovery of the excitatory process.

A third possible explanation of the experimental results is that physiological masking results from a line-busy effect, but that the post-stimulus depression, which causes the effect, recovers much more slowly than the refractory period of myelinated nerve fibers. This hypothesis leads to a straightforward explanation of all the results thus far obtained. We must, however, make one qualification. Since repetitive firing of single auditory-nerve fibers occurs at rates of up to 1 000/sec (Tasaki, 1954; Kiang et al., 1963; Rose et al., 1967), the slowly recovering, post-stimulus depression must be conceived of as having an effect on the probability of firing throughout the responding population rather than as having an invariant effect on each fiber.

It is well known that recovery processes in unmyelinated nerve fibers are much slower than in myelinated fibers, and it is therefore tempting to place the hypothetical, slowly recovering process in the unmyelinated auditory-nerve endings, which extend from the habenula perforata to the terminations on the hair cells. Since post-stimulus depression in unmyelinated nerve fibers is cumulative, even with relatively long interstimulus intervals, this hypothesis can account for the masking-duration effect.

Previous experiments established that shortening masking duration increases recovery rate (Coats, 1964 a). At very short masking durations (less than 50 msec), the time required for recovery approaches a limit of about 50–100 msec. If we assume that only a single process (a slowly recovering poststimulus depression of excitability) accounts for masking, then the click-pair recovery situation can be regarded as equivalent to shortening the masking stimulus to the limit. The increased rate of click-pair recovery produced by masking is then easily explained, since it is logical to assume that those fibers which still respond to the click in the presence of the masking stimulus are (or tend to be) more rapidly recovering.

The observed effects of masking on latency can also be explained in a straightforward way. At high click intensities, where relative increase in latency with masking is greatest, the masking stimulus would be expected to eliminate from the population responding to the click only those fibers with relatively low thresholds. The presynaptic excitatory process would then take longer to reach the thresholds of the remaining fibers, thus causing a latency increase with a qualitative similarity to the latency increase produced by cooling and attenuation. However, the latency increase would be determined by the distribution of thresholds among the population of responding fibers rather than the rise time of the excitatory process—hence, the observed quantitative difference.

At intermediate test-click intensities, latency would be expected to increase as masking intensity increased from low levels. But as masking intensity reaches and surpasses the highest thresholds of the fibers responding to the click,

Discussion

In this attempt to interpret the above results, the following assumptions are implicit. (1) The whole-nerve AP amplitude is determined by the number of fibers firing synchronously in response to the click. Alterations in AP amplitude are produced by changing the number of synchronously firing fibers. (2) The AP peak latency is determined by the modal latency of the single-fiber responses

Effects of cooling and attenuation

In a previous report (Coats 1965) we speculated that the quantitatively equal effects of cooling and attenuation on AP latency were due to the two treatments having a common mechnism of action We further suggested that cooling and attenuation slow the rise time (hence increasing AP latency) and reduce the amplitude (hence decreasing AP amplitude) of a hypothetical cochlear excitatory process. Since the change in microphonic amplitude caused by cooling and attenuation differed by an order of magnitude this hypothetical excitatory process must be central to the microphonic generator

The present results establish that temperature and stimulus intensity have qualitatively similar effects on masking recovery and quantitatively equal effects on click pair recovery This enlarged list of similarities between temperature and stimulus intensity further supports the thesis that the two treatments act via a common mechanism.

The broadening of the N_1 peak which occurs with cooling and attenuation is easily compatible with this hypothesis since it could be attributed to the well known increased variability of single-fiber response latency which occurs near threshold

Our data do not rule out the possibility that temperature affects the click AP by direct action on the nerve fibers rather than on the process which excites the nerve fibers. However if we assume a direct temperature effect on the auditory nerve fibers, it becomes difficult to explain the similarities between cooling and attenuation since attenuation would not be expected to change spike height or threshold of individual nerve fibers.

Effect of masking

The slight latency increase accompanying masking could be explained by assuming that a traveling wave, which begins at the basilar end of the cochlear partition and moves apically generates the click AP and by also assuming that the masking stimulus selectively removes the responses of basilar fibers. However this explanation is considered unlikely because the present investigation shows no differential masking-frequency effect on AP latency

It seems probable that in the present investigation we are dealing with a patch of sensory epithelium and its associated afferent nerve fibers which respond more or less equally to all stimulus frequencies (Tasaki & Fernández, 1952 Kiang et al. 1963) The results must therefore be explained on the basis of the neurophysiological properties of this system rather than its mechanical properties.

One way to explain the latency increase produced by masking is to assume that two mechanisms are operative—one, the classical line-busy mechanism the other depression of the hypothetical presynaptic" cochlear excitatory process (Coats, 1964 *a*) The line-busy mechanism would not be expected to increase latency and could therefore be invoked to account for most of the AP reduction produced by masking. Depressing the presynaptic process could then be regarded as a secondary effect which would account for the slight latency increase having the same qualitative properties as the latency increase produced by cooling and attenuation Recovery of the excitatory process would also explain why recovery from masking is much slower than would be expected if only the line busy mechanism were operative

the probability of a given fiber's being masked would be determined less and less by threshold, and latency would therefore decline again toward control values.

The relatively small latency change at low click intensities is also easily accounted for since we would expect the threshold range of fibers responding to the low intensity click to be relatively small.

Summary

We compared the effects of cooling, stimulus attenuation and physiological masking on the gross click action-potential (AP) and found that. (1) cooling and attenuation produce equal increases in AP latency (2) cooling and attenuation have equal effects on click pair recovery and on masking recovery (3) masking increases AP latency but by a much smaller amount than cooling and attenuation, and the effect is dependent on masking and test-click intensity (4) the frequency of the masking stimulus has no effect on the amount of increase in masked AP latency (5) during onset of and recovery from masking, AP latency and AP amplitude appear time locked. The results are most easily explained if we assume that: (1) cooling and attenuation act on a postmicrophonic cochlear excitatory process, (2) the mechanism of physiological masking is a line-busy effect, but the poststimulus depression of excitability recovers much more slowly than the refractory period of myelinated nerve fibers.

Zusammenfassung

Wir haben die Wirkungen von Kühlung, Reizabschwächung und physiologischer Maskierung auf den gesamten Klick Aktionspotentialen (AP) miteinander verglichen und dabei herausgefunden, dass (1) Kühlung und Abschwächung gleiche Zunahme von AP Latenz hervorrufen (2) Kühlung und Abschwächung gleiche Wirkungen auf Klick Paar Wiederherstellung und Maskierungs-Wiederherstellung haben (3) Maskierung die AP Latenz verstärkt jedoch in sehr viel geringerem Masse als Kühlung und Abschwächung, und die Wirkung hängt von der Maskierung und von der Test Klick Intensität ab (4) die Frequenz des Maskierungsreizes keine Wirkung auf das Mass der Zunahme bei maskierter AP Latenz hat (5) während des Anfalls und der Genesung von Maskierung, AP Latenz und AP Umfang zeitgebunden erscheinen. Die Ergebnisse sind höchst einfach zu erklären, wenn wir annehmen dass. (1) Kühlung und Abschwächung in einem postmikrophonischen Reizungsprozess vorsichgehen, (2) der Mechanismus der physiologischen Maskierung ein dauertönender Effekt ist, aber dass die nachwirkende Schwäche der Erregbarkeit sich sehr viel langsamer wieder erholt als die langanhaltende Periode myelinierter Nervenfasern.

CONTENTS

I Introduction

The mouse provides excellent material for the study of the normal and abnormal development of the mammalian inner ear. It lends itself to the study of hereditary malformations of the inner ear because there are twenty-five known genes affecting the inner ear of the mouse and some of these lead to lesions which resemble lesions occurring in man.

Various investigators have studied aspects of the normal development of the inner ear of the mouse in order to evaluate deviations from the normal pattern of development. M. S. Deol (1, 2, 3, 4), Kikuchi and Hilding (9), Gruneberg, Hallpike and Ledoux (5) and Truslove (19) have studied the differentiation of a number of mutant strains. Each of these authors has described some features of the differentiation of the inner ear of the normal mouse. Ingalls, Kelemen, and Curley (7) in discussing the effect of hypoxia on the development of the inner ears of embryos of pregnant mice, discuss features of the inner ears of the neonates.

Mikaelian and Ruben (12) have studied the correlation of the appearance of the cochlear potential, nerve action potentials, and behavioral responses with the cochlear anatomy in the developing mouse. They have described some aspects of the postnatal anatomical development of the inner ear. Otis and Brent (14) in comparing the rate of development of the human embryo with that of the mouse embryo, have timed the appearance of some of the major features of the otic labyrinth in the mouse.

Weibel (20) used the light microscope to make a detailed morphological study of the inner ear of the mouse after birth. He did not deal with the details of the differentiation processes taking place before birth. Kikuchi and Hilding (8) used phase contrast and electron microscopy to study the maturation of the organ of Corti in mice from birth to adulthood. They also studied the development of the stria vascularis in mice after birth (10). Ruben (17) has studied the developmental pattern of terminal mitoses in the membranous labyrinth. Ramon y Cajal (15) and Tello (18) have studied the pattern of innervation of the developing inner ear of the mouse.

None of the above studies provides a comprehensive histological picture of the embryological and postnatal development of the inner ear of the mouse. This report provides a day by day analysis of the anatomical and histological changes taking place in the inner ear of the normal mouse from the eleventh day of gestation to the tenth day after birth. The development of the patterns of innervation of the vestibular apparatus and cochlear duct is discussed. It is hoped that this paper will facilitate comparative studies of the embryonic and postnatal development of the malformed inner ears of the many genetically deaf strains with that of the normal organ. It also will provide a model of *in vivo* development of the normal inner ear by which the progress of mouse otocysts grown *in vitro* can be measured.

I Introduction

The mouse provides excellent material for the study of the normal and abnormal development of the mammalian inner ear. It lends itself to the study of hereditary malformations of the inner ear because there are twenty five known genes affecting the inner ear of the mouse and some of these lead to lesions which resemble lesions occurring in man.

Various investigators have studied aspects of the normal development of the inner ear of the mouse in order to evaluate deviations from the normal pattern of development. M. S. Deol (1 2 3 4) Kikuchi and Hilding (9) Grüneberg, Hallpike and Ledoux (5) and Truslove (19) have studied the differentiation of a number of mutant strains. Each of these authors has described some features of the differentiation of the inner ear of the normal mouse. Ingalls, Kelemen, and Curley (7) in discussing the effect of hypoxia on the development of the inner ears of embryos of pregnant mice, discuss features of the inner ears of the neonates.

Mikaelian and Ruben (1) have studied the correlation of the appearance of the cochlear potential, nerve action potentials, and behavioral responses with the cochlear anatomy in the developing mouse. They have described some aspects of the postnatal anatomical development of the inner ear. Otis and Brent (14), in comparing the rate of development of the human embryo with that of the mouse embryo, have timed the appearance of some of the major features of the otic labyrinth in the mouse.

Weibel (20) used the light microscope to make a detailed morphological study of the inner ear of the mouse after birth. He did not deal with the details of the differentiation processes taking place before birth. Kikuchi and Hilding (8) used phase contrast and electron microscopy to study the maturation of the organ of Corti in mice from birth to adulthood. They also studied the development of the stria vascularis in mice after birth (10). Ruben (17) has studied the developmental pattern of terminal mitoses in the membranous labyrinth. Ramon y Cajal (15) and Tello (18) have studied the pattern of innervation of the developing inner ear of the mouse.

None of the above studies provides a comprehensive histological picture of the embryological and postnatal development of the inner ear of the mouse. This report provides a day by day analysis of the anatomical and histological changes taking place in the inner ear of the normal mouse from the eleventh day of gestation to the tenth day after birth. The development of the patterns of innervation of the vestibular apparatus and cochlear duct is discussed. It is hoped that this paper will facilitate comparative studies of the embryonic and postnatal development of the malformed inner ears of the many genetically deaf strains with that of the normal organ. It also will provide a model of in vivo development of the normal inner ear by which the progress of mouse otocysts grown in vitro can be measured.

II Procedure

Tissue processing

A series of twenty two embryos and twenty young mice of the CBA J/CBA J strain was studied Either two or four embryos for each day of gestation from the eleventh to the nine teenth were examined. Similarly two mice were sacrificed on each day after birth from the first to the tenth.

Ears from two different litters were ex amined from the eleventh day of gestation through the sixteenth day of gestation Ears from members of only one litter per day were used for the observations on the remainder of the days Only one ear of each specimen was analyzed Right or left ears were used on a random basis No significant differences were found between ears of litter mates or those of non-litter mates of the same age In one case only a difference in development equivalent to about one half day of gestation was noted between two non litter mates of the same age.

Dating of the embryos was accomplished by means of the vaginal plug method. Males and females were put together in one cage over night and the females were checked for vagi nal plugs at 8 00 a m the following day The day when the plug was observed was called the first day of gestation The day of birth was called the first day postpartum All of the postpartum animals studied were born on the twentieth day of gestation.

The pregnant females were sacrificed on the appropriate day by cervical dislocation The abdomen was opened and the embryos were removed from the uterus and placed in a 0 9% solution of sodium chloride in water Embryos older than sixteen days were decapitated and only their heads were preserved The em bryos were fixed in 10% Acrolein solution buffered with phosphate to pH 7 4 Embryos younger than sixteen days were kept in the Acrolein solution for three hours. The heads of embryos seventeen days or older were placed in Acrolein overnight at four degrees Centigrade in the refrigerator

The postpartum mice were decapitated. The skin and mandible were removed from the head. The nose was cut off anterior to the eyes and the head was divided in the sagittal plane. Each part was then placed in the Acrolein solution for twenty four hours.

After fixation specimens were washed in tap water for one-half hour Specimens younger than fifteen days of gestation were then de hydrated in a 1 1 (v/v) solution of ethylene glycol monomethyl ether and methyl alcohol for forty eight hours. This solution will be referred to as M & M Specimens older than fifteen days of gestation were decalcified before being dehydrated This was accomplished over a three-day period by a 10% solution of di-sodium ethylenediamine tetra acetate (EDTA) with 2 5% of polyvinylpyrrolidone buffered to pH 7 2 with a Tris hydroxymethyl amino-methane buffer The specimens were then washed in tap water for one half hour and dehydrated in M & M for three to five days.

Those specimens which had been decal cified in EDTA were after being dehydrated in M & M placed in 2% celloidin dissolved in 1 1 ethylene glycol monomethyl ether and methyl alcohol for twenty four hours This was followed by hardening in chloroform for twelve hours This last procedure was not carried out with those specimens which had not been decalcified

All specimens were placed in 90 poly ethylene glycol 400-distearate and 10 cetyl alcohol (w/w) at thirty seven degrees Centi grade for 72 hours. The tissue was embedded in the polyethylene glycol 400-distearate and cetyl alcohol and was placed in the refrigerator until it was sectioned

Embryos of thirteen days of gestation or

less were sectioned at 5 microns. Those of *fourteen* to seventeen days of gestation were sectioned at 7 microns. All specimens older than seventeen days of gestation were sectioned at 10 microns. All sections were serially mounted.

At least one specimen at each age was stained with Harris hematoxylin and eosin Y. One specimen at each level of development was stained by the Protargol technique of Rasmussen and McCrane (16).

Methods of observation

The degree of coiling of the cochlear duct was determined for each specimen by an adaptation of the graphic reconstruction method of Guild (6). This method projects the turns of the cochlear duct onto a common plane perpendicular to the axis of the cochlear duct. The method described by Guild uses as its baseline the center of the unions of the outer and inner pillar cells. In the early embryological inner ear the cochlear duct has not undergone sufficient cytological differentiation to allow identification of inner and outer pillar cells. Therefore the tangent to the outermost cells of the undifferentiated axial wall of the cochlear duct was used to reconstruct these early cochlear ducts.

III Development of the Otic Labyrinth

A Eleventh and Twelfth Day Otocysts

The eleventh day otocyst is a closed ovoid sac (Plate 1 Fig. A). The dorsal part of the caudo-lateral wall consists of simple cuboidal epithelium, and the dorsal part of the medial wall is made up of pseudostratified columnar epithelium *with two to three layers of nuclei*. The cells of the caudal and rostral walls are pseudostratified columnar and merge with the simple low cuboidal cells of the caudo-lateral wall. The ventral part of the otocyst consists entirely of pseudostratified epithelium with about three layers of nuclei.

At the twelfth day of gestation the endolymphatic duct has developed as an evagination from the medial wall of the otocyst about one-third of the way from the dorsal to the ventral ends (*Plate 1 Fig. B*). *The walls of* the endolymphatic duct consist of simple cuboidal *epithelium*. The medial and lateral walls of the dorsal part of the twelve day otocyst are made up of simple cuboidal epithelium. The rostral and caudal surfaces of the dorsal part are pseudostratified columnar epithelium (Plate 1 Fig. C). Ventral to the opening of the endolymphatic duct the walls of the otocyst are pseudostratified columnar epithelium (Plate 1 *Fig. D*). Thus, while the dorsal portion of the otocyst consists largely of simple epithelium, *the nuclei of the ventral part are stratified in two to three layers*. The ganglion of the eighth nerve lies medial and somewhat rostral to the thicker ventral part of the otocyst (Plate 1 Fig. D). A ridge of pseudostratified columnar epithelium is present on the lateral wall, directly opposite the point where the endolymphatic duct meets the otocyst (Plate 1 Fig. B). The ridge is where the utriculoendolymphatic valve *and utriculosaccular duct* will form.

B Development of the Semicircular Ducts

The superior semicircular duct is the first semicircular duct to develop. It appears *in its most* rudimentary *form* between the twelfth and thirteenth *days of gestation* as a pouch of epi-

II Procedure

Tissue processing

A series of twenty two embryos and twenty young mice of the CBA J/CBA J strain was studied Either two or four embryos for each day of gestation from the eleventh to the nineteenth were examined. Similarly two mice were sacrificed on each day after birth from the first to the tenth

Ears from two different litters were examined from the eleventh day of gestation through the sixteenth day of gestation Ears from members of only one litter per day were used for the observations on the remainder of the days. Only one ear of each specimen was analyzed Right or left ears were used on a random basis. No significant differences were found between ears of litter mates or those of non litter mates of the same age. In one case only a difference in development equivalent to about one half day of gestation was noted between two non-litter mates of the same age

Dating of the embryos was accomplished by means of the vaginal plug method Males and females were put together in one cage over night, and the females were checked for vaginal plugs at 8 00 a m the following day The day when the plug was observed was called the first day of gestation The day of birth was called the first day postpartum All of the postpartum animals studied were born on the twentieth day of gestation

The pregnant females were sacrificed on the appropriate day by cervical dislocation The abdomen was opened and the embryos were removed from the uterus and placed in a 0 9% solution of sodium chloride in water Embryos older than sixteen days were decapitated and only their heads were preserved. The embryos were fixed in 10% Acrolein solution buffered with phosphate to pH 7 4 Embryos younger than sixteen days were kept in the Acrolein solution for three hours The heads of embryos seventeen days or older were placed in Acrolein overnight at four degrees Centrigrade in the refrigerator

The postpartum mice were decapitated. The skin and mandible were removed from the head The nose was cut off anterior to the eyes and the head was divided in the sagittal plane. Each part was then placed in the Acrolein solution for twenty four hours

After fixation specimens were washed in tap water for one-half hour Specimens younger than fifteen days of gestation were then dehydrated in a 1 1 (v/v) solution of ethylene glycol monomethyl ether and methyl alcohol for forty eight hours. This solution will be referred to as M & M Specimens older than fifteen days of gestation were decalcified before being dehydrated This was accomplished over a three-day period by a 10% solution of disodium ethylenediamine tetra acetate (EDTA) with 2.5% of polyvinylpyrrolidone buffered to pH 7 2 with a Tris hydroxymethyl aminomethane buffer The specimens were then washed in tap water for one half hour and dehydrated in M & M for three to five days.

Those specimens which had been decalcified in EDTA were after being dehydrated in M & M placed in 2% celloidin dissolved in 1 1 ethylene glycol monomethyl ether and methyl alcohol for twenty four hours. This was followed by hardening in chloroform for twelve hours This last procedure was not carried out with those specimens which had not been decalcified

All specimens were placed in 90% polyethylene glycol 400-distearate and 10% cetyl alcohol (w w) at thirty seven degrees Centigrade for 72 hours. The tissue was embedded in the polyethylene glycol 400-distearate and cetyl alcohol and was placed in the refrigerator until it was sectioned

Embryos of thirteen days of gestation or

together at the opening of the saccule. It does not extend across the opening of the utricle. The valve is considerably longer on the seventeenth day of gestation, extending laterally across the opening of the utricle (Plate 4 Fig. B). It changes the configuration of the utriculosaccular connection from a straight line to a right angle bend by covering the mouth of the utricle. It also causes the endolymphatic duct to flow directly into the saccule. The valve is made up of the low cuboidal epithelium of the utricular wall, the slightly taller cuboidal epithelium of the endolymphatic duct, and the periotic tissue of the vestibule between the two epithelial layers (Plate 4 Fig. C) The utriculoendolymphatic valve has grown into a crescent shaped flap at nineteen days and completely covers the opening of the utricle. The concave side of the flap faces inside the utricle (Plate 4 Figs. D and E).

The maculae of the utricle and saccule start to differentiate between the thirteenth and fourteenth days of gestation. In the thirteen day embryo there is a small portion of the wall of the otocyst which has five to six layers of densely packed nuclei topped by a layer of eosinophilic cytoplasm. This region is located at the point where the rostral loop of the superior semicircular duct opens into the utricle (Plate 5 Figs. A and B) It may be the forerunner of sensory epithelium of the crista of the superior semicircular duct or of the macula of the utricle. The maculae of both the utricle and saccule have clearly differentiated at the fourteenth day of gestation (Plate 5 Fig. C). The macula of the utricle is present on the lateral and rostral walls of the utricle in the vicinity of the ampulla of the lateral semicircular duct. The macula of the saccule is located on the medial wall of the saccule. On the fourteenth day of gestation both maculae have a stratum of supporting cells which contains five to six rows of densely packed nuclei and is topped by a single row of tall columnar cells. The latter appear to be the precursors of the sensory cells. They are much larger than the supporting cells and have a great deal of very clear eosinophilic cytoplasm. The cytoplasm of the supporting cells is not seen and the nuclei are closely packed. The nuclei of the sensory cells are much larger than the nuclei of the supporting cells. The nuclei of the supporting cells have heavy chromatin markings, whereas the nuclei of the sensory cells are almost glassy clear with few dark areas. Any chromatin markings that are present are much fainter and smaller than those in the supporting cells. On the sixteenth day there appears to be less interdigitation between sensory and supporting cells than on the preceding days of development (Plate 6 Fig. A) In some regions there is a space between the top layer of cells and those below On the seventeenth day this gap is still apparent (Plate 6 Fig. B). It may be artifactual, or it may represent an anatomic separation between the sensory and supporting cells.

Between the fourteenth and seventeenth days the nuclei of the tall columnar cells become progressively larger and more glassy in appearance. From the sixteenth to the eighteenth days of gestation the number of rows of supporting cell nuclei in the maculae decreases to two or three (Plate 6 Fig. C) Only one layer of supporting cell nuclei is present on the nineteenth day (Plate 6, Fig. D) The result is stratified epithelium of two layers. On the nineteenth day the sensory cell nuclei are large, round and much lighter staining than the nuclei of the supporting cells. The nuclei of the supporting cells are ovoid and have heavier and more numerous chromatin spots than the sensory cell nuclei. Almost no cytoplasm is visible around the supporting cell nuclei, but the sensory cells have a great deal of cytoplasm and are about three times as tall as they are wide. Otoconia are present for the first time on the seventeenth day The number of otoconia increases considerably on the eighteenth and nineteenth days. On the day of birth both maculae have thick otolithic membranes with large numbers of otoconia.

The non-maculated walls of the utricle and saccule consist of simple cuboidal epithelium.

thelium projecting from the dorsal wall of the otocyst. The opposite walls of the pouch come together in the center but the pouch remains patent along its rim. The superior semicircular duct is completed by the thirteenth day of gestation. Its walls are simple high cuboidal epithelium except on the convex side of the duct, where the wall appears to be pseudostratified cuboidal (Plate 2 Fig. A) The posterior semicircular duct develops about one half day after the superior duct.

At thirteen days it is represented by an evagination from the ventral part of the caudal end of the utricle (Plate 2 Fig. B) No crus commune is present. At this stage of development there is no sign of lateral semicircular duct formation

On the fourteenth day of gestation all three semicircular ducts are present. Their walls are made up of simple cuboidal epithelium except on their convex sides where there appears to be pseudostratified cuboidal epithelium with two to three strata of nuclei (Plate 2 Fig. C) The crus commune is formed By the fourteenth day there is an ampulla on each of the three ducts. Each ampulla at fourteen days has a crista (Plate 2 Fig. D) On the fourteenth day of gestation the walls of the ampullae opposite the cristae consist of simple tall cuboidal epithelium They remain as simple epithelium in their further development, but the cells gradually become flatter (Plate 2 Fig. E) By the nineteenth day the day before birth they are very low cuboidal and by the tenth day postpartum they are squamous cells.

The cristae are papillae which on the fourteenth day of gestation have a stratum of supporting cells with five to six levels of closely packed nuclei This stratum is topped by a single layer of tall columnar cells (Plate 3 Fig A) There is little cytoplasm in the supporting cells The supporting cell nuclei are ovoid and have numerous darkly staining basophilic granules The cells in the top row have a great deal of clear eosinophilic cytoplasm and large, clear basal nuclei They may be the forerunners of the sensory epithelium of the cristae. Their nuclei are larger and paler staining than the supporting cell nuclei below On the seventeenth day of gestation the periotic connective tissue and fibers of the eighth nerve are present in the papilla of supporting cells so that the cristae have cores of connective tissue (Plate 3 Fig. B) The number of strata of supporting cell nuclei has decreased to three or four At the nineteenth day of development the number of layers of supporting cell nuclei has decreased to less than three from the original five to six layers (Plate 3 Fig. C). In some regions there is only one layer of supporting cell nuclei On the first day after birth the cristae have one layer of supporting cells topped by a layer of sensory cells (Plate 3 Fig. D) The sensory cells are tall columnar cells about three times as tall as they are wide. Their nuclei are round and lighter staining than the ovoid nuclei of the supporting cells. The chromatin of the sensory cell nuclei is much finer and less clumped than that of the supporting cell nuclei. The cristae are well differentiated by the first day after birth.

C Development of the Utricle Saccule and Utriculoendolymphatic Valve

The first step toward separation of the membranous labyrinth into utricle and saccule occurs on the fifteenth day of gestation A constriction appears in the region of the origin of the endolymphatic duct and represents the beginning of formation of the utriculosaccular duct (Plate 4 Fig. A) The newly separated utricle and saccule lie along a straight line, and the utriculosaccular duct at this stage of development is a straight channel The endolymphatic duct lies medial to the utricle and opens into the short utriculosaccular duct.

The utriculoendolymphatic valve is present in rudimentary form on the fifteenth day of gestation. It is represented by a small fold of tissue consisting of the reflection of the epithelial walls of the utricle and endolymphatic duct at the point where the two structures flow

together at the opening of the saccule. It does not extend across the opening of the utricle. The valve is considerably longer on the seventeenth day of gestation, extending laterally across the opening of the utricle (Plate 4 Fig. B). It changes the configuration of the utriculosaccular connection from a straight line to a right angle bend by covering the mouth of the utricle. It also causes the endolymphatic duct to flow directly into the saccule. The valve is made up of the low cuboidal epithelium of the utricular wall, the slightly taller cuboidal epithelium of the endolymphatic duct, and the periotic tissue of the vestibule between the two epithelial layers (Plate 4 Fig. C). The utriculoendolymphatic valve has grown into a crescent shaped flap at nineteen days and completely covers the opening of the utricle. The concave side of the flap faces inside the utricle (Plate 4 Figs D and E).

The maculae of the utricle and saccule start to differentiate between the thirteenth and fourteenth days of gestation. In the thirteen day embryo there is a small portion of the wall of the otocyst which has five to six layers of densely packed nuclei topped by a layer of eosinophilic cytoplasm. This region is located at the point where the rostral loop of the superior semicircular duct opens into the utricle (Plate 5 Figs. A and B). It may be the forerunner of sensory epithelium of the crista of the superior semicircular duct or of the macula of the utricle. The maculae of both the utricle and saccule have clearly differentiated at the fourteenth day of gestation (Plate 5 Fig. C). The macula of the utricle is present on the lateral and rostral walls of the utricle in the vicinity of the ampulla of the lateral semicircular duct. The macula of the saccule is located on the medial wall of the saccule. On the fourteenth day of gestation both maculae have a stratum of supporting cells which contains five to six rows of densely packed nuclei and is topped by a single row of tall columnar cells. The latter appear to be the precursors of the sensory cells. They are much larger than the supporting cells and have a great deal of very clear eosinophilic cytoplasm. The cytoplasm of the supporting cells is not seen and the nuclei are closely packed. The nuclei of the sensory cells are much larger than the nuclei of the supporting cells. The nuclei of the supporting cells have heavy chromatin markings, whereas the nuclei of the sensory cells are almost glassy clear with few dark areas. Any chromatin markings that are present are much fainter and smaller than those in the supporting cells. On the sixteenth day there appears to be less interdigitation between sensory and supporting cells than on the preceding days of development (Plate 6 Fig. A). In some regions there is a space between the top layer of cells and those below. On the seventeenth day this gap is still apparent (Plate 6, Fig. B). It may be artifactual, or it may represent an anatomic separation between the sensory and supporting cells.

Between the fourteenth and seventeenth days the nuclei of the tall columnar cells become progressively larger and more glassy in appearance. From the sixteenth to the eighteenth days of gestation the number of rows of supporting cell nuclei in the maculae decreases to two or three (Plate 6 Fig. C). Only one layer of supporting cell nuclei is present on the nineteenth day (Plate 6 Fig. D). The result is stratified epithelium of two layers. On the nineteenth day the sensory cell nuclei are large, round and much lighter staining than the nuclei of the supporting cells. The nuclei of the supporting cells are ovoid and have heavier and more numerous chromatin spots than the sensory cell nuclei. Almost no cytoplasm is visible around the supporting cell nuclei, but the sensory cells have a great deal of cytoplasm and are about three times as tall as they are wide. Otoconia are present for the first time on the seventeenth day. The number of otoconia increases considerably on the eighteenth and nineteenth days. On the day of birth both maculae have thick otolithic membranes with large numbers of otoconia.

The non-maculated walls of the utricle and saccule consist of simple cuboidal epithelium.

thelium projecting from the dorsal wall of the otocyst. The opposite walls of the pouch come together in the center but the pouch remains patent along its rim. The superior semicircular duct is completed by the thirteenth day of gestation. Its walls are simple high cuboidal epithelium except on the convex side of the duct where the wall appears to be pseudostratified cuboidal (Plate 2 Fig. A). The posterior semicircular duct develops about one half day after the superior duct.

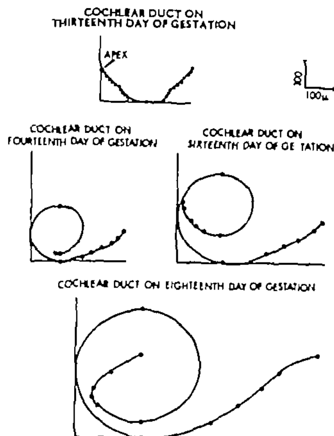
At thirteen days it is represented by an evagination from the ventral part of the caudal end of the utricle (Plate 2 Fig. B). No crus commune is present. At this stage of development there is no sign of lateral semicircular duct formation.

On the fourteenth day of gestation all three semicircular ducts are present. Their walls are made up of simple cuboidal epithelium except on their convex sides where there appears to be pseudostratified cuboidal epithelium with two to three strata of nuclei (Plate 2 Fig. C). The crus commune is formed. By the fourteenth day there is an ampulla on each of the three ducts. Each ampulla at fourteen days has a crista (Plate 2 Fig. D). On the fourteenth day of gestation the walls of the ampullae opposite the cristae consist of simple tall cuboidal epithelium. They remain as simple epithelium in their further development but the cells gradually become flatter (Plate 2 Fig. E). By the nineteenth day, the day before birth, they are very low cuboidal and by the tenth day postpartum they are squamous cells.

The cristae are papillae which on the fourteenth day of gestation have a stratum of supporting cells with five to six levels of closely packed nuclei. This stratum is topped by a single layer of tall columnar cells (Plate 3 Fig. A). There is little cytoplasm in the supporting cells. The supporting cell nuclei are ovoid and have numerous darkly staining basophilic granules. The cells in the top row have a great deal of clear eosinophilic cytoplasm and large, clear basal nuclei. They may be the forerunners of the sensory epithelium of the cristae. Their nuclei are larger and paler staining than the supporting cell nuclei below. On the seventeenth day of gestation the periotic connective tissue and fibers of the eighth nerve are present in the papilla of supporting cells so that the cristae have cores of connective tissue (Plate 3 Fig. B). The number of strata of supporting cell nuclei has decreased to three or four. At the nineteenth day of development the number of layers of supporting cell nuclei has decreased to less than three from the original five to six layers (Plate 3 Fig. C). In some regions there is only one layer of supporting cell nuclei. On the first day after birth the cristae have one layer of supporting cells topped by a layer of sensory cells (Plate 3 Fig. D). The sensory cells are tall columnar cells about three times as tall as they are wide. Their nuclei are round and lighter staining than the ovoid nuclei of the supporting cells. The chromatin of the sensory cell nuclei is much finer and less clumped than that of the supporting cell nuclei. The cristae are well differentiated by the first day after birth.

C Development of the Utricle Saccule, and Utriculoendolymphatic Valve

*The first step toward separation of the mem*branous labyrinth into utricle and saccule occurs on the fifteenth day of gestation. A constriction appears in the region of the origin of the endolymphatic duct and represents the beginning of formation of the utriculosaccular duct (Plate 4 Fig. A). The newly separated utricle and saccule lie along a straight line and the utriculosaccular duct at this stage of development is a straight channel. The endolymphatic duct lies medial to the utricle and opens into the short utriculosaccular duct.



The utriculoendolymphatic valve is present in rudimentary form on the fifteenth day of gestation. It is represented by a small fold of tissue consisting of the reflection of the epithelial walls of the utricle and endolymphatic duct at the point where the two structures flow

together at the opening of the saccule. It does not extend across the opening of the utricle. The valve is considerably longer on the seventeenth day of gestation, extending laterally across the opening of the utricle (Plate 4 Fig. B) It changes the configuration of the utriculosaccular connection from a straight line to a right angle bend by covering the mouth of the utricle. It also causes the endolymphatic duct to flow directly into the saccule. The valve is made up of the low cuboidal epithelium of the utricular wall the slightly taller cuboidal epithelium of the endolymphatic duct, and the periotic tissue of the vestibule between the two epithelial layers (Plate 4 Fig. C). The utriculoendolymphatic valve has grown into a crescent shaped flap at nineteen days and completely covers the opening of the utricle. The concave side of the flap faces inside the utricle (Plate 4 Figs. D and F)

The maculae of the utricle and saccule start to differentiate between the thirteenth and fourteenth days of gestation. In the thirteen day embryo there is a small portion of the wall of the otocyst which has five to six layers of densely packed nuclei topped by a layer of eosinophilic cytoplasm. This region is located at the point where the rostral loop of the superior semicircular duct opens into the utricle (Plate 5 Figs. A and B). It may be the forerunner of sensory epithelium of the crista of the superior semicircular duct or of the macula of the utricle. The maculae of both the utricle and saccule have clearly differentiated at the fourteenth day of gestation (Plate 5 Fig. C). The macula of the utricle is present on the lateral and rostral walls of the utricle in the vicinity of the ampulla of the lateral semicircular duct. The macula of the saccule is located on the medial wall of the saccule. On the fourteenth day of gestation both maculae have a stratum of supporting cells which contains five to six rows of densely packed nuclei and is topped by a single row of tall columnar cells. The latter appear to be the precursors of the sensory cells. They are much larger than the supporting cells and have a great deal of very clear eosinophilic cytoplasm. The cytoplasm of the supporting cells is not seen and the nuclei are closely packed. The nuclei of the sensory cells are much larger than the nuclei of the supporting cells. The nuclei of the supporting cells have heavy chromatin markings, whereas the nuclei of the sensory cells are almost glassy clear with few dark areas. Any chromatin markings that are present are much fainter and smaller than those in the supporting cells. On the sixteenth day there appears to be less interdigitation between sensory and supporting cells than on the preceding days of development (Plate 6 Fig. A) In some regions there is a space between the top layer of cells and those below On the seventeenth day this gap is still apparent (Plate 6, Fig. B) It may be artifactual, or it may represent an anatomic separation between the sensory and supporting cells.

Between the fourteenth and seventeenth days the nuclei of the tall columnar cells become progressively larger and more glassy in appearance. From the sixteenth to the eighteenth days of gestation the number of rows of supporting cell nuclei in the maculae decreases to two or three (Plate 6, Fig. C) Only one layer of supporting cell nuclei is present on the nineteenth day (Plate 6, Fig. D). The result is stratified epithelium of two layers. On the nineteenth day the sensory cell nuclei are large round and much lighter staining than the nuclei of the supporting cells. The nuclei of the supporting cells are ovoid and have heavier and more numerous chromatin spots than the sensory cell nuclei. Almost no cytoplasm is visible around the supporting cell nuclei, but the sensory cells have a great deal of cytoplasm and are about three times as tall as they are wide. Otoconia are present for the first time on the seventeenth day The number of otoconia increases considerably on the eighteenth and nineteenth days. On the day of birth both maculae have thick otolithic membranes with large numbers of otoconia.

The non-maculated walls of the utricle and saccule consist of simple cuboidal epithelium.

Graph 1 Development of the cochlear duct The reconstructions demonstrate the increase in size and *degree of coiling* of the cochlear duct from the thirteenth to the eighteenth days of gestation

D Development of the Cochlear Duct

1 Formation of cochlear duct and ductus reuniens

The cochlear duct starts to develop between the twelfth and thirteenth days of gestation as an extension of the ventral part of the otocyst The thirteen day embryo has about one-*half turn* of cochlear duct The duct has the form of a half coil with a hook near the distal end (Graph 1) There is no ductus reuniens, and a wide channel connects the cochlear duct with the vestibular labyrinth The cochlear duct on the fourteenth day is about one and one-quarter coils long (Graph 1) On the fifteenth day the wide channel between the cochlear duct and the saccule begins to narrow This forerunner of the ductus reuniens consists of pseudostratified epithelium with two layers of nuclei on its lateral side and more than five layers on its medial side (Plate 7 Fig. A) The thicker side is continuous *dorsally* with the macula of *the saccule* and ventrally with the thick caudal wall of the cochlear duct.

On the sixteenth day of gestation the cochlear duct has about one and one-half coils (Graph 1) The ductus reuniens is well defined. Its lateral wall consists of simple cuboidal epithelium and its medial wall consists of pseudostratified cuboidal epithelium (Plate 7 Fig. B) Between the seventeenth and eighteenth days of gestation the cochlear duct has between one and one half and one and three-quarters coils There is no further coiling of the cochlear duct (Graph 1) On the eighteenth day of gestation all of the walls of the ductus reuniens consist of simple cuboidal epithelium (Plate 7 Fig. C)

2. Differentiation of the organ of Corti

The cochlear duct on the thirteenth day has two types of walls (Plate 8 Fig. A) The rostral wall consists of epithelium with two to three layers of tightly packed nuclei The caudal wall has six layers of tightly packed nuclei

The caudal wall of the cochlear duct is the site of differentiation of the organ of Corti. On the thirteenth day of development differentiation into sensory and supporting cells has not taken place On the fourteenth day the caudal wall has differentiated into a layer of supporting cells containing five to six strata of nuclei The supporting cell layer is topped by a layer of tall columnar cells which have basal nuclei and clear eosinophilic cytoplasm (Plate 8 Fig. B) It resembles the maculae of the utricle and saccule on the same day of development.

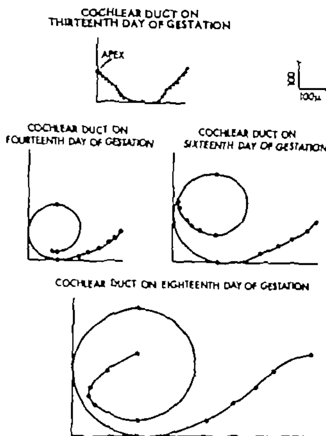
The appearance of the caudal wall does not change significantly on the fifteenth and sixteenth days of gestation (Plate 8 Figs. C D E) The sensory cells in the cochlear duct have more cytoplasm than the supporting cells. However unlike the sensory cell nuclei of the maculae of the utricle and saccule, the nuclei of the sensory cells of the cochlear duct are not markedly different from the nuclei of the supporting cells

On the seventeenth day the sensory cells in the lateral portion of the basal third of the duct show signs of differentiation into three outer hair cells, one inner hair cell, and phalangeal cells (Plate 9 Figs. A, B). The hair cells rest on a layer of supporting cells that has one to two strata of nuclei. The nuclei of the hair cells stand somewhat higher than the nuclei of adjacent cells. Between the outer hair cells and the inner hair cell is an area of highly vacuolated cytoplasm. The caudal wall of the apical two-thirds of the cochlear duct has not progressed in differentiation from the sixteenth day (Plate 9 Figs. C D).

The area which will form the tunnel of Corti has become apparent in the basal and middle coils on the eighteenth day of development (Plate 10 Figs. A, B C). The cytoplasm is vacuolated and gives the appearance of a space. However there is still a cell in the space as cytoplasm and nuclei can be seen. Three outer and one inner hair cells flank the tunnel. They rest on a layer of supporting cells which, in the basal coil, has a single layer of nuclei. In the middle portion of the cochlear duct there are two to three layers of supporting cell nuclei beneath the hair cells. The differentiation of the apical coil on the eighteenth day is not significantly greater than on the seventeenth day (Plate 10 Fig. D)

The outer and inner hair cells have differentiated throughout the length of the cochlear duct on the nineteenth day of gestation (Plate 11 Fig. A) At nineteen days of gestation the tunnel of Corti is forming. The inner and outer hair cells are tilted over the tunnel in such a way that their apices lean toward one another The region of the tunnel is not a free space but consists of vacuolated cytoplasm. There are nuclei in the space where the tunnel is forming. The pillar shaped cytoplasmic processes of the inner and outer pillar cells are not differentiated. The pillar cells gradually become thinner after the birth of the animal.

The tectorial membrane begins to form by the first day postpartum. It is represented at that time by a thin strip of pale eosinophilic material over the cells in the region where the sulcus spiralis internus will form (Plate 11 Fig B). This is the first day on which a definitive structure representing the tectorial membrane is visible. On previous days small areas of pale eosinophilic material could occasionally be identified in the region where the tectorial membrane later develops. These may represent earlier stages of tectorial membrane formation. Different staining techniques would help to determine on which day of development formation of the tectorial membrane commences. The tectorial membrane thickens on subsequent days of development (Plate 12 Figs. A B, C)



Between the fifth and sixth days postpartum the nuclei of the inner and outer pillar cells move to opposite sides of the tunnel of Corti (Plate 12, Figs. A, B). The pillar cells attain their mature shape on the tenth day post partum. The tunnel of Corti becomes wider between the eighth and tenth days after birth (Plate 12, Figs. C, D)

Between the eighth and tenth days post partum the hair cells become narrower This narrowing process leaves large gaps between the outer hair cells. The Deiters cells and the inner phalangeal cells become very vacuolated on the eighth and ninth days postpartum. On the tenth day these cells are very slender and there are large spaces between them. Thus, the space of Nuel is well differentiated by the tenth day postpartum (Plate 12, Figs. C D).

3 Differentiation of the limbus spiralis

The limbus spiralis starts to differentiate between the seventeenth and eighteenth days of gestation. In the eighteen day embryo, development of the limbus is limited to the basal coil of the cochlear duct, where the axial portion of the caudal wall has become simple cuboidal epithelium (Plate 10 Figs. A B C, D). Beneath this epithelial layer is highly cellular condensed mesenchyme.

On the nineteenth day the middle coil is

Graph 1 Development of the cochlear duct The reconstructions demonstrate the increase in size and degree of coiling of the cochlear duct from the thirteenth to the eighteenth days of gestation

D Development of the Cochlear Duct

1 *Formation of cochlear duct and ductus reuniens*

The cochlear duct starts to develop between the twelfth and thirteenth days of gestation as an extension of the ventral part of the otocyst. The thirteen day embryo has about one half turn of cochlear duct. The duct has the form of a half coil with a hook near the distal end (Graph 1) There is no ductus reuniens, and a wide channel connects the cochlear duct with the vestibular labyrinth The cochlear duct on the fourteenth day is about one and one-quarter coils long (Graph 1) On the fifteenth day the wide channel between the cochlear duct and the saccule begins to narrow This forerunner of the ductus reuniens consists of pseudostratified epithelium with two layers of nuclei on its lateral side and more than five layers on its medial side (Plate 7 Fig. A) The thicker side is continuous dorsally with the macula of the saccule and ventrally with the thick caudal wall of the cochlear duct.

On the sixteenth day of gestation the cochlear duct has about one and one half coils (Graph 1) The ductus reuniens is well defined Its lateral wall consists of simple cuboidal epithelium and its medial wall consists of pseudostratified cuboidal epithelium (Plate 7 Fig B) Between the seventeenth and eighteenth days of gestation the cochlear duct has between one and one-half and one and three-quarters coils. There is no further coiling of the cochlear duct (Graph 1) On the eighteenth day of gestation all of the walls of the ductus reuniens consist of simple cuboidal epithelium (Plate 7 Fig. C)

2. Differentiation of the organ of Corti

The cochlear duct on the thirteenth day has two types of walls (Plate 8 Fig. A) The rostral wall consists of epithelium with two to three layers of tightly packed nuclei. The caudal wall has six layers of tightly packed nuclei.

The caudal wall of the cochlear duct is the site of differentiation of the organ of Corti. On the thirteenth day of development differentiation into sensory and supporting cells has not taken place On the fourteenth day the caudal wall has differentiated into a layer of supporting cells containing five to six strata of nuclei. The supporting cell layer is topped by a layer of tall columnar cells which have basal nuclei and clear eosinophilic cytoplasm (Plate 8 Fig. B) It resembles the maculae of the utricle and saccule on the same day of development.

The appearance of the caudal wall does not change significantly on the fifteenth and sixteenth days of gestation (Plate 8 Figs. C D E) The sensory cells in the cochlear duct have more cytoplasm than the supporting cells However unlike the sensory cell nuclei of the maculae of the utricle and saccule, the nuclei of the sensory cells of the cochlear duct are not markedly different from the nuclei of the supporting cells.

On the seventeenth day the sensory cells in the lateral portion of the basal third of the duct show signs of differentiation into three outer hair cells, one inner hair cell, and phalangeal cells (Plate 9 Figs. A, B). The hair cells rest on a layer of supporting cells that has one to two strata of nuclei. The nuclei of the hair cells stand somewhat higher than the nuclei of adjacent cells. Between the outer hair cells and the inner hair cell is an area of highly vacuolated cytoplasm. The caudal wall of the apical two-thirds of the cochlear duct has not progressed in differentiation from the sixteenth day (Plate 9 Figs. C D).

The area which will form the tunnel of Corti has become apparent in the basal and middle coils on the eighteenth day of development (Plate 10 Figs. A, B, C). The cytoplasm is vacuolated and gives the appearance of a space However there is still a cell in the space as cytoplasm and nuclei can be seen. Three outer and one inner hair cells flank the tunnel. They rest on a layer of supporting cells which, in the basal coil, has a single layer of nuclei In the middle portion of the cochlear duct there are two to three layers of supporting cell nuclei beneath the hair cells. The differentiation of the apical coil on the eighteenth day is not significantly greater than on the seventeenth day (Plate 10 Fig. D).

The outer and inner hair cells have differentiated throughout the length of the cochlear duct on the nineteenth day of gestation (Plate 11 Fig. A) At nineteen days of gestation the tunnel of Corti is forming. The inner and outer hair cells are tilted over the tunnel in such a way that their apices lean toward one another The region of the tunnel is not a free space but consists of vacuolated cytoplasm. There are nuclei in the space where the tunnel is forming. The pillar shaped cytoplasmic processes of the inner and outer pillar cells are not differentiated. The pillar cells gradually become thinner after the birth of the animal.

The tectorial membrane begins to form by the first day postpartum. It is represented at that time by a thin strip of pale eosinophilic material over the cells in the region where the sulcus spiralis internus will form (Plate 11 Fig. B). Thus is the first day on which a definitive structure representing the tectorial membrane is visible. On previous days small areas of pale eosinophilic material could occasionally be identified in the region where the tectorial membrane later develops. These may represent earlier stages of tectorial membrane formation. Different staining techniques would help to determine on which day of development formation of the tectorial membrane commences. The tectorial membrane thickens on subsequent days of development (Plate 12, Figs. A, B C).

Between the fifth and sixth days postpartum the nuclei of the inner and outer pillar cells move to opposite sides of the tunnel of Corti (Plate 12, Figs. A, B). The pillar cells attain their mature shape on the tenth day postpartum. The tunnel of Corti becomes wider between the eighth and tenth days after birth (Plate 12, Figs. C D)

Between the eighth and tenth days postpartum the hair cells become narrower This narrowing process leaves large gaps between the outer hair cells. The Deiters cells and the inner phalangeal cells become very vacuolated on the eighth and ninth days postpartum. On the tenth day these cells are very slender and there are large spaces between them. Thus, the space of Nuel is well differentiated by the tenth day postpartum (Plate 12, Figs. C, D).

3 Differentiation of the limbus spiralis

The limbus spiralis starts to differentiate between the seventeenth and eighteenth days of gestation. In the eighteen day embryo, development of the limbus is limited to the basal coil of the cochlear duct, where the axial portion of the caudal wall has become simple cuboidal epithelium (Plate 10, Figs. A, B, C, D). Beneath this epithelial layer is highly cellular condensed mesenchyme.

On the nineteenth day the middle coil is

starting to differentiate into limbus, and the epithelial layer in the region of differentiation has about two strata of nuclei (Plate 13 Fig. A) In the basal coil the mesenchyme under the epithelium has become less cellular than it was at eighteen days and there is more extracellular matrix.

On the first day after birth the limbus is differentiated throughout the cochlear duct except for the extreme apex (Plate 13 Figs B C D) The limbus has started to develop in the apical coil but its epithelial wall has two to three strata of nuclei The connective tissue under the limbus in the basal and middle coils has a great deal of extracellular matrix. The region immediately adjacent to the epithelium consists almost entirely of extracellular matrix

On the fourth day after birth the limbus spiralis has formed throughout the cochlear duct. It consists of a mound of connective tissue covered by simple tall cuboidal epithelium with a single stratum of long thin nuclei Beneath the epithelium there is a wide band of connective tissue containing few cells The cell density of the connective tissue decreases in later development

4 Differentiation of the sulcus spiralis internus

The sulcus spiralis internus starts to develop after the first day postpartum On the first day postpartum the region just lateral to the limbus is still occupied by four to five layers of nuclei and a surface layer of eosinophilic cytoplasm (Plate 13 Figs. B C D) The epithelium is similar to that of the undifferentiated wall of the cochlear duct at sixteen days of gestation. On the second day after birth the cytoplasm of these cells is slightly vacuolated (Plate 14 Fig. A)

The number of layers of nuclei in the basal coil in the region of the sulcus has decreased to two or three by the sixth day after birth (Plate 14 Fig. B) Large amounts of cytoplasm in the sulcus region appear to have disintegrated The middle coil also has only two to three layers of nuclei in the region of the sulcus. The cytoplasm is degenerating and is filled with large vacuoles. Cytoplasmic disintegration is less complete than in the basal coil The apical coil shows little differentiation. On the seventh day the apical coil shows considerable vacuolization (Plate 14 Fig. C)

By the tenth day postpartum the sulcus spiralis internus has formed throughout the cochlear duct. It is lined by a layer of simple low cuboidal epithelium (Plate 14 Fig. D)

5 Differentiation of Reissner's membrane

Reissner's membrane develops from the rostral wall of the cochlear duct. The rostral wall of the cochlear duct of the thirteen day embryo consists of epithelium with two to three layers of tightly packed nuclei (Plate 15 Fig. A) On the fourteenth day of gestation the rostral wall still has two to three layers of nuclei but the extreme medial and lateral portions of the wall consist of simple columnar epithelium (Plate 15 Fig. B) The rostral wall of the fifteen day cochlear duct shows large areas particularly in the apical coil which have become simple cuboidal epithelium On the sixteenth day the rostral wall is composed of simple cuboidal epithelium throughout the duct (Plate 15 Figs. C D) This represents the inner cell layer of Reissner's membrane

On the nineteenth day of gestation, parts of the rostral wall of the basal turn have two layers of cells (Plate 16 Fig. A) The layer derived from the otocyst is simple cuboidal epithelium. Closely applied to this, on the outer surface is a single layer of long, thin cells The latter are derived from the mesenchyme surrounding the otocyst and remain when the scala vestibuli forms The other areas of the basal and middle coils have two to three layers of mesenchyme adjacent to the epithelial wall The apical coil has a thick condensation of mesenchyme adjacent to the epithelial wall since the scala vestibuli has not yet formed in the apical turn (Plate 16 Fig B) By the third day after birth the rostral wall of the entire basal and middle coils have been reduced to two layers of cells with only occasional adherence of additional mesenchymal cells to the

periotic side of the membrane. Reissner's membrane has differentiated throughout all turns of the cochlear duct by the fourth day after birth (Plate 16, Fig. C). On subsequent days of development, it appears stretched and somewhat thinner.

6. Differentiation of the stria vascularis

The stria vascularis starts to differentiate on the seventeenth day of gestation (Plate 17 Fig. A). A condensation of mesenchyme develops adjacent to the outer part of the rostral wall of the cochlear duct. This condensation contains many capillaries. On the nineteenth day the condensation is denser (Plate 17 Fig. B). The wall of the cochlear duct in this region consists of simple cuboidal epithelium. The cuboidal epithelial cells in the part of the wall adjacent to the condensed mesenchyme have nuclei that are slightly smaller and stain more intensely than those of the cells in the adjacent parts of the epithelial wall which are not developing into stria.

On the first day after birth the boundary between the epithelial wall and the underlying connective tissue is less distinct (Plate 17 Fig. C). The epithelial cells have become smaller and their nuclei are intensely stained with hematoxylin. The nuclei, which had been ovoid to round, are now elongated with the long axis of the nuclei at right angles to the plane of the connective tissue surface. The cells appear dentate, with projections going into the mesenchyme.

On the second day postpartum no sharp boundary is discernible between the epithelial wall and the condensed connective tissue (Plate 17 Fig. D). Between the second and third days after birth the mesenchyme becomes more compact. The cells are more tightly packed and their nuclei are smaller and more darkly staining.

On the fourth day there are two limiting walls of the stria (Plate 17 Fig. E). The inner one is derived from the otocyst. The outer one is from the mesenchyme. In between are capillaries intermingled with connective tissue cells. In subsequent development, the connective tissue of the stria becomes less cellular. It is still more cellular than the adult stria at ten days after birth.

IV Development of the Scala Vestibuli and Scala Tympani

On the twelfth day of gestation the mesenchyme around the otocyst is somewhat condensed. It is relatively sparse adjacent to the dorsal half of the otocyst and more dense adjacent to the ventral portion. At thirteen days the mesenchyme surrounding the otocyst is more condensed than at twelve days. The cochlear duct is completely surrounded by a layer of dense mesenchyme. On the fourteenth day of embryonic development the mesenchyme surrounding the cochlear duct shows differentiation into two concentric rings (Plate 18 Fig. A). The inner ring is less dense than the outer ring. Its interstitial substance stains more lightly and the nuclei are smaller. The nuclei in the outer, more darkly staining ring are larger and rounder than the ovoid nuclei of the inner zone. On the fifteenth day the outermost ring has considerable extracellular matrix and is starting to resemble cartilagenous tissue (Plate 18, Fig. B). Inside this newly forming cartilage is a region of loose connective tissue which shows regions of decreased density. No scala tympani or scala vestibuli have formed. On the sixteenth day there is still no differentiation of scalae vestibuli and tympani. The connective tissue in the inner ring is very sparse and the cytoplasm of the cells of this region form very fine trabeculae. The nuclei are small and stain darkly. The nuclei of the

surrounding ring are much larger and some what lighter staining There is a dense region of connective tissue cells lining the inner aspect of the cartilage ring

On the eighteenth day of gestation the scalae tympani and vestibuli have formed around the basal coil (Plate 18 *Fig.* C) They are represented by open cavities in the mass of connective tissue and are crossed by oc casional fine trabeculae Two to three layers of mesenchyme are condensed against the ves tibular side of Reissner's membrane. In the middle portion of the cochlear duct the scalae are forming and the mesenchyme is extremely thin and trabeculated. Around the apex of the cochlear duct there are no scalae

On the second day after birth the scalae ves tibuli and tympani have both reached the apex of the cochlear duct (Plate 18 Fig. D). The *helicotrema* is not completely differentiated, but there are only a few strands of tissue separating the scalae. On the fourth day the helicotrema is well formed (Plate 18 Fig. E).

V Development of the Innervation of the Vestibular Apparatus and Cochlear Duct

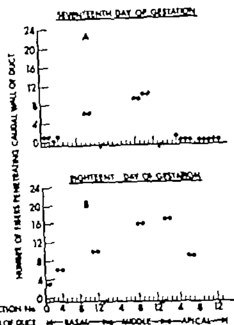
A Development of the Ganglia of the Eighth Nerve

The seventh and eighth cranial nerve ganglia are represented by one cell mass in the twelve day embryo (*Plate 19 Fig* A) The facial-stato-acoustic ganglion lies medial to the ven tral part of the otocyst The mass of nerve cells splits ventrally into a medial part the acoustic ganglion and a lateral part the geniculate ganglion (Plate 19 Fig B) Fibers from both ganglia penetrate the brain by the twelfth day of gestation

On the thirteenth day of gestation the stato-acoustic ganglion shows internal differentia tion indicating which part will develop into the vestibular ganglion and which will form the spiral ganglion (Plate 19 Fig C) At about the level of the rudimentary posterior semicircular duct, which is ventral to the point at which seventh and eighth ganglia diverge from each other the eighth ganglion is differentiated into lateral and medial portions The medial por tion of the ganglion has nuclei which are more densely packed than the nuclei of the lateral portion The lateral half does not extend as far ventrad as the medial half and represents the forerunner of the vestibular ganglion. The medial half terminates in the loop between the ventral end of the saccule and the newly formed half coil of the cochlear duct. It is the primordium of the spiral ganglion.

On the fourteenth day the spiral ganglion extends under one complete turn of the coch-lear duct (Plate 19 Fig. D) The duct itself has about one and one quarter turns, but no spiral ganglion cells are visible under the last quarter turn. At fifteen days, the seventh and eighth ganglia are still contiguous. There is also no physical separation of the vestibular and the spiral ganglia. Between the sixteenth and seventeenth days, the vestibular and the spiral ganglia have separated considerably In the eighteen day embryo the two ganglia are separate

The geniculate ganglion and the vestibular ganglion are not completely separate until the first day after birth. Until that time there is a sparse accumulation of ganglion cells in the gap between the two ganglia (Plate 19 Fig. E)



Between the seventeenth and eighteenth days of gestation the cochlear duct attains its full number of coils, and the spiral ganglion ex tends to the apical coil.

B Innervation of the Vestibular Apparatus and Cochlear Duct

The twelfth day otocyst is innervated by fibers from the acoustic ganglion. There are no fibers innervating the otocyst dorsal to the point where the endolymphatic duct flows into it. Ventral to this level the ganglion lies in close proximity to the rostral wall of the otocyst (Plate 20 Fig. A). A bundle of fibers extends laterad from this portion of the ganglion, runs around the rostral end of the otocyst, and penetrates the *rostral part of the lateral* wall. The wall of the otocyst contains three to four layers of nuclei in this region and the nerve fibers penetrate to the innermost layer (Plate 20 Fig. B).

The thirteenth day otocyst is more extensively innervated than the twelfth day otocyst. Most dorsally a bundle of fibers innervates the rostral wall of the otocyst at the level where the endolymphatic duct flows in (Plate 21 Fig. A). Ventral to this a bundle of fibers extends laterad from the ganglion, circumscribes the rostral edge of the otocyst, and innervates its lateral wall (Plate 21 Fig. B). The outermost fibers of the bundle run the longest distance and penetrate the lateral wall opposite the opening of the endolymphatic duct. The inner fibers of the bundle do not extend as far caudad, and they penetrate the wall near the rostral end. The wall contains four to five strata of nuclei and the fibers *penetrate to the innermost stratum* (Plate 21 Fig. C). Ventral to this a third fiber bundle extends from the ganglion to the medial side of the rostral portion of the otocyst (Plate 22, Fig. A). The fibers do not penetrate as deeply and are considerably less numerous than the fibers to the lateral wall (*Plate 22, Fig. B*). The most ventral fiber bundle originates in the ventral end of the ganglion. It extends ventrad and caudad along the medial side of the otocyst to innervate the rudimentary posterior semicircular duct (Plate 22, *Fig. C*).

Those fiber bundles already present on the thirteenth day of gestation are thicker on the fourteenth day. On the fourteenth day they are seen to represent the major fiber bundles of the adult. The most dorsal fiber bundle runs laterad from the ganglion at the level of the macula of the utricle and the lateral semicircular duct (Plate 23 Fig. A). *Some fibers extend dorsad from this bundle to the crista of the superior semicircular duct. The remaining fibers continue laterad. The inner fibers extend only as far as the rostral portion of the macula of the utricle* (*Plate 23 Fig. B*). *The outer fibers continue laterad past the utricle to the crista of the lateral semicircular duct. Ventral to this bundle, in the region of the saccule, bundles of fibers extend from the ganglion to the medial wall of the saccule,*

Graphs 2A and 2B. Nerve fiber penetration of caudal wall of cochlear duct on seventeenth and eighteenth days of gestation. Each cochlear duct studied was considered as being composed of three equal parts: basal, middle and apical portions. Each portion was studied individually. Thirteen equally spaced microscopic sections of each portion, from the beginning to the end of that portion, were analyzed. Using oil immersion (×1 000) and focusing in all planes, the number of nerve fibers penetrating the caudal wall of the duct was counted.

surrounding ring are much larger and somewhat lighter staining. There is a dense region of connective tissue cells lining the inner aspect of the cartilage ring.

On the eighteenth day of gestation the scalae tympani and vestibuli have formed around the basal coil (Plate 18 Fig C) They are represented by open cavities in the mass of connective tissue and are crossed by occasional fine trabeculae Two to three layers of mesenchyme are condensed against the vestibular side of Reissner's membrane In the middle portion of the cochlear duct the scalae are forming, and the mesenchyme is extremely thin and trabeculated. Around the apex of the cochlear duct there are no scalae.

On the second day after birth the scalae vestibuli and tympani have both reached the apex of the cochlear duct (Plate 18 Fig. D) The helicotrema is not completely differentiated but there are only a few strands of tissue separating the scalae. On the fourth day the helicotrema is well formed (Plate 18 Fig. E)

V Development of the Innervation of the Vestibular Apparatus and Cochlear Duct

A Development of the Ganglia of the Eighth Nerve

The seventh and eighth cranial nerve ganglia are represented by one cell mass in the twelve day embryo (Plate 19 Fig. A) The facial-stato-acoustic ganglion lies medial to the ventral part of the otocyst. The mass of nerve cells splits ventrally into a medial part, the acoustic ganglion and a lateral part the geniculate ganglion (Plate 19 Fig B) Fibers from both ganglia penetrate the brain by the twelfth day of gestation

On the thirteenth day of gestation the stato-acoustic ganglion shows internal differentiation indicating which part will develop into the vestibular ganglion and which will form the spiral ganglion (Plate 19 Fig. C) At about the level of the rudimentary posterior semicircular duct which is ventral to the point at which seventh and eighth ganglia diverge from each other the eighth ganglion is differentiated into lateral and medial portions The medial portion of the ganglion has nuclei which are more densely packed than the nuclei of the lateral portion The lateral half does not extend as far ventrad as the medial half and represents the forerunner of the vestibular ganglion. The medial half terminates in the loop between the ventral end of the saccule and the newly formed half coil of the cochlear duct It is the primordium of the spiral ganglion

On the fourteenth day the spiral ganglion extends under one complete turn of the cochlear duct (Plate 19 Fig. D) The duct itself has about one and one quarter turns but no spiral ganglion cells are visible under the last quarter turn. At fifteen days the seventh and eighth ganglia are still contiguous. There is also no physical separation of the vestibular and the spiral ganglia. Between the sixteenth and seventeenth days, the vestibular and the spiral ganglia have separated considerably In the eighteen day embryo the two ganglia are separate.

The geniculate ganglion and the vestibular ganglion are not completely separate until the first day after birth Until that time there is a sparse accumulation of ganglion cells in the gap between the two ganglia (Plate 19 Fig. E)

Between the seventeenth and eighteenth days of gestation the cochlear duct attains its full number of coils, and the spiral ganglion extends to the apical coil.

and Hilding, using phase contrast microscopy have found that the internal tunnel begins to open at about the sixth day postpartum and is complete by the tenth day after birth (8)

The inner and outer hair cells, tunnel of Corti, internal sulcus and limbus spiralis differentiate in the basal coil first, and differentiation proceeds upward toward the apex. This confirms Weibel's observations (20) Kikuchi and Hilding similarly found that the tunnel of Corti begins to open at the basal end and moves upward toward the apex (8)

Kikuchi and Hilding have shown with the electron microscope that differentiation of the stria vascularis proceeds from base to apex and that by ten days after birth the adult pattern is reached (10) Mikaelian and Ruben report that the stria attains normal adult dimensions by the eighth day postpartum (12) Weibel states that by the second day after birth the stria vascularis has reached its final structure (20). He comes to this conclusion by comparing the two-day old ear with that of a nine-day old mouse. It was found in the present study that even at ten days postpartum the stria appears immature. On the tenth day postpartum the stria is still more cellular than the adult stria.

Weibel states that the limbus spiralis is complete by the sixth day postpartum. The present study indicates that the limbus is not fully developed even at ten days postpartum. As early as the fourth day postpartum, all components of the limbus are present. However on the tenth day after birth, the structure is far more cellular than the adult limbus.

Innervation of the sensory areas of the inner ear precedes differentiation of the epithelium. The otocyst is innervated by fibers of the eighth nerve on the twelfth day of gestation. On the thirteenth day of embryonic development the fibers of the eighth nerve have divided up into the fiber bundles which appear to be those characteristic of the adult animal. These include an upper bundle to the cristae of the superior and lateral semicircular ducts and the macula of the utricle, and more ventral fiber bundles to the macula of the saccule and to the crista of the posterior semicircular duct. All of these fiber bundles on the thirteenth day innervate regions which have not differentiated into sensory epithelium. However all three cristae of the semi-circular ducts and the two maculae are recognizable on the fourteenth day On the fourteenth day of gestation the epithelium of the maculae and cristae have clearly differentiated into sensory and supporting cells. Similarly differentiation of the epithelium of the cochlear duct follows the earliest innervation of the duct. When the first half coil develops on the thirteenth day there is no differentiation of the basal epithelium. However fibers from the spiral ganglion already penetrate the cochlear duct epithelium on the thirteenth day

Knowlton (11) has reported that histogenesis of sensory areas in the inner ear of the embryonic chick is correlated with neural development. She reports that the sequence in the sensory area begins with penetration of sensory epithelia by acoustic dendrites. This is followed by a chemical change in the primordial sensory cell cytoplasm, formation of primitive covering membranes, and segregation of sensory and supporting cells. The appearance of a discrete nerve branch in the chick precedes subdivision of a sensory region.

Orr (13) has reported that embryonic chick otocysts and associated tissues cultivated in organ culture developed completely differentiated sensory epithelial membranes of the inner ear Enzymatically dissociated otocysts reassociated and, if they were supported by mesenchyme, developed into sensory membranes composed of hair cells and supporting cells. Cytodifferentiation of hair cells of innervated membranes was complete, whereas differentiation of hair cells in noninnervated membranes was retarded. Innervation was necessary for complete cytodifferentiation of hair cells in reconstructed epithelial membranes.

The fact that nerve fiber penetration precedes differentiation of the epithelial wall in the normal mouse inner ear suggests that the

where the macula is forming (Plate 23 Figs C D) They are not organized into a well formed fiber bundle and the innervation of the saccule is not as dense as that of the utricle. The most ventral fiber bundle runs caudad and ventrad from the ventral end of the vestibular ganglion and innervates the crista of the posterior semicircular duct (Plate 23 Fig. E)

The sensory epithelium of the vestibular apparatus is already innervated on the thirteenth day before differentiation of that epithelium into a macula or a crista occurs.

The epithelium of the caudal wall of the cochlear duct is innervated on the thirteenth day of gestation when only one half coil has formed (Plate 24 Fig. A) The spiral ganglion expands as the cochlear duct develops more coils. On the seventeenth day of gestation the middle portion of the cochlear is most heavily innervated (Graph 2 A) The basal coil is innervated less extensively and the apical coil shows almost no innervation On the eighteenth day of gestation the middle portion is still more heavily innervated than either the apical or basal portions of the duct (Graph 2 B) On subsequent days of development all portions of the cochlear duct are heavily innervated. By the second day after birth it is clear that the fibers innervating the cochlear duct include both radial and longitudinal fibers (Plate 24 Fig. B)

VI Discussion

The membranous labyrinth which is represented by an ovoid sac on the eleventh day of gestation has all of the major components of the adult inner ear when the mouse is born Postnatal development takes the form of cytological differentiation rather than the formation of gross structures.

The semicircular ducts and the cochlear duct both start to develop between the twelfth and thirteenth days of gestation The superior duct forms before the posterior duct. The lateral duct is the latest in developing It has been similarly reported that in the chick the vertical canals are formed before the horizontal canal (13) Between the seventeenth and eighteenth days of gestation the cochlear duct attains its full number of coils. Weibel reports that on the thirteenth day of embryonic development the cochlear duct describes one complete winding (20) However it was found in the present study that on the thirteenth day the cochlear duct had only about one half coil.

The differentiation of sensory and supporting cells begins on the fourteenth day of gestation throughout the cristae, maculae and cochlear duct. Differentiation of the inner and outer hair cells starts on the seventeenth day of gestation Mikaelian and Ruben report that the hair cells appear to be mature by the eighth day postpartum (12) The present study indicates that between the eighth and tenth day the hair cells and phalangeal cells become narrower with the result that spaces are formed between them The hair cells appear mature by the tenth day after birth. Differences such as this are in part accounted for by the different histological techniques used in the preparation of the tissues Mikaelian and Ruben fixed their specimens with 10 formalin and embedded them in celloidin The specimens used in the present study were fixed in 10% Acrolein and embedded in polyester wax

The cupulae of the cristae were not preserved in the tissue sections There was eosinophilic material resembling rudimentary tectorial membrane as early as the sixteenth day of gestation However it was not observed consistently until the first day after birth

The pillar cells and internal tunnel appear complete by the tenth day postpartum. Kikuchi

nerve fibers may play a role in inducing the differentiation of the sensory epithelium in the mouse. The work of Knowlton and Orr suggest that this may be true in the chick These relationships among the different elements in the developing inner ear of the mammal could be studied more thoroughly in mouse otocysts grown *in vitro* in the absence of the eighth nerve ganglion

VII Summary

This report provides a day by day analysis of the anatomic and histological changes taking place in the inner ear of the normal mouse from the eleventh day of gestation to the tenth day after birth. An atlas of photomicrographs illustrates the developmental processes. The formation of the patterns of innervation of the vestibular apparatus and cochlear duct is discussed It was found that the membranous labyrinth develops all of the major components of the adult inner ear before birth and that postnatal development takes the form of cytological differentiation rather than the formation of gross structures. Differentiation of the cochlear duct proceeds from base to apex. Innervation of the sensory areas of the inner ear precedes differentiation of the epithelium. The possibility that the nerve fibers have an inductive effect on the undifferentiated epithelium is discussed

Zusammenfassung

Dieser Bericht umfasst eine täglich fortlaufende Analyse anatomischer und histologischer Veränderungen des inneren Ohres einer normalen Maus vom 11 Tag der Trächtigkeit bis zum 10 Tag nach der Geburt. Ein Atlas mit Photomikrographien veranschaulicht den Entwicklungsprozess. Die Entstehung der Innervationsrhythmen des Vestibularapparates und des Cochlearganges wurde beschrieben Es wurde festgestellt, dass das Membranlabyrinth die Hauptbestandteile des ausgewachsenen Innerohres vor der Geburt entwickelt und dass die postnatale Entwicklung nur die Form cytologischer Differenzierung und nicht die Form grosser Strukturen einnimmt. Die Differenzierung des Cochlearkanales verlauft von der Basis zur Spitze Die Innervation der sensorischen Gebiete des inneren Ohres geht der Differenzierung des Epithels voraus Die Möglichkeit eines induktiven Effektes der Nervenfasern auf das undifferenzierte Epithel wurde besprochen.

VIII Acknowledgement

The author wishes to express his thanks to the National Institute of Neurological Disease and Blindness for giving him the opportunity to carry out these investigations. The study was initiated at New York University School of Medicine Department of Otorhinolaryngology and completed at the Albert Einstein College of Medicine Department of Otorhinolaryngology The work was carried out in the laboratory of Dr Robert J Ruben, whose guidance, criticism and aid are gratefully acknowledged Miss Aracelis Colmenares prepared the histological specimens, and Mr Milton Kurtz prepared the photomicrographs Mr Thomas Van De Water offered many helpful suggestions throughout the study

nerve fibers may play a role in inducing the differentiation of the sensory epithelium in the mouse. The work of Knowlton and Orr suggest that this may be true in the chick These relationships among the different elements in the developing inner ear of the mammal could be studied more thoroughly in mouse otocysts grown *in vitro* in the absence of the eighth nerve ganglion

VII Summary

This report provides a day by day analysis of the anatomic and histological changes taking place in the inner ear of the normal mouse from the eleventh day of gestation to the tenth day after birth. An atlas of photomicrographs illustrates the developmental processes. The formation of the patterns of innervation of the vestibular apparatus and cochlear duct is discussed It was found that the membranous labyrinth develops all of the major components of the adult inner ear before birth and that postnatal development takes the form of cytological differentiation rather than the formation of gross structures Differentiation of the cochlear duct proceeds from base to apex. Innervation of the sensory areas of the inner ear precedes differentiation of the epithelium. The possibility that the nerve fibers have an inductive effect on the undifferentiated epithelium is discussed.

Zusammenfassung

Dieser Bericht umfasst eine täglich fortlaufende Analyse anatomischer und histologischer Veränderungen des inneren Ohres einer normalen Maus vom 11 Tag der Trächtigkeit bis zum 10 Tag nach der Geburt. Ein Atlas mit Photomikrographien veranschaulicht den Entwicklungsprozess. Die Entstehung der Innervationsrhythmen des Vestibularapparates und des Cochlearganges wurde beschrieben. Es wurde festgestellt, dass das Membranlabyrinth die Hauptbestandteile des ausgewachsenen Innerohres vor der Geburt entwickelt und dass die postnatale Entwicklung nur die Form cytologischer Differenzierung und nicht die Form grosser Strukturen einnimmt. Die Differenzierung des Cochlearkanales verläuft von der Basis zur Spitze. Die Innervation der sensorischen Gebiete des inneren Ohres geht der Differenzierung des Epithels voraus Die Möglichkeit eines induktiven Effektes der Nervenfasern auf das undifferenzierte Epithel wurde besprochen.

VIII Acknowledgement

The author wishes to express his thanks to the National Institute of Neurological Disease and Blindness for giving him the opportunity to carry out these investigations. The study was initiated at New York University School of Medicine Department of Otorhinolaryngology and completed at the Albert Einstein College of Medicine Department of Otorhinolaryngology The work was carried out in the laboratory of Dr Robert J Ruben whose guidance criticism and aid are gratefully acknowledged. Miss Aracelis Colmenares prepared the histological specimens, and Mr Milton Kurtz prepared the photomicrographs. Mr Thomas Van De Water offered many helpful suggestions throughout the study

Appendix

	Endolymphatic duct and sac	Utriculosaccular duct and utriculoendolymphatic valve	Semicircular ducts	Cristae of semicircular ducts
18 G. D.				
19 G. D				Number of layers of supporting cell nuclei has decreased to less than three. In some areas there is only one layer
1 P. P				The cristae has only one layer of supporting cells topped by single layer of sensory cells

Table I

In the following tables, G D refers to days of gestation and P P refers to days postpartum.

	Endolymphatic duct and sac	Utriculosaccular duct and utriculoendolymphatic valve	Semicircular ducts	Cristae of semicircular ducts
12 G D	Endolymphatic duct is present ends blindly consists of simple high cuboidal epithelium			
13 G D			Superior duct is complete, Posterior duct is starting to form and is represented by an evagination from ventral part of caudal end of utricle. No crus commune is present No sign of formation of lateral duct	
14 G D	Blind end of duct has enlarged to form endolymphatic sac Walls of duct and sac consist of simple cuboidal epithelium	None There is wide open channel between utricle and saccule	All 3 ducts are formed. Walls consist of simple cuboidal epithelium except for pseudostratified cuboidal epithelium on convex sides. Crus commune is present. All 3 ducts have ampullae of simple tall cuboidal epithelium	All 3 semicircular ducts have cristae which consist of a stratum of supporting cells with 5 to 6 layers of nuclei topped by a single layer of tall columnar cells
15 G D		Constriction exists in region of endolymphatic duct and is the anlage of the utriculosaccular duct There is Y-shaped confluence of utricle, saccule, and endolymphatic duct Utricle and saccule lie along straight line so utriculossacular duct is linear Utriculoendolymphatic valve is present in rudimentary form		
16 G D				
17 G D		Utriculoendolymphatic valve extends across the opening of the utricle It has converted duct into utriculoendolymphatic and sacculoendolymphatic ducts which meet at a right angle at the origin of the endolymphatic duct Walls of ducts are simple cuboidal cells		Periotic connective tissue and fibers of eighth cranial nerve have pushed up into the cores of the cristae

	Endolymphatic duct and sac	Utriculosaccular duct and utriculoendolymphatic valve	Semicircular ducts	Cristae of semicircular ducts
18 G D				
19 G D				Number of layers of supporting cell nuclei has decreased to less than three. In some areas there is only one layer
1 P P				The cristae has only one layer of supporting cells topped by a single layer of sensory cells

Table II

	Maculae of utricle and saccule	Number of coils of cochlear duct	Formation of ductus reuniens	Differentiation of inner and outer hair and pha langeal cells	Internal tunnel differentiation
12 G D.		0			
13 G D	In region where rostral loop of superior duct flows into utricle the wall has 6 layers of supporting cell nuclei topped by single layer of tall cells, May be anlage of macula of utricle or of crista	1/2	There is none, There is wide open channel between cochlear duct and rest of otocyst		
14 G D	Maculae of utricle and sac cule formed Consist of a stratum of supporting cells with 5 to 6 layers nuclei topped by a single layer of tall columnar cells	1 1/4		Entire caudal wall of cochlear duct consists of a stratum of supporting cells with 5 to 6 layers of nuclei topped by a single layer of columnar cells	
15 G D		1 1/4	Starting to form, Wide channel between cochlear duct and saccule has narrowed. Ductus reuniens forerunner has - layers of nuclei on its lateral side and 5 to 6 layers on its medial side		
16 G D	There is less interdigitation between supporting and sensory cells than on previous days. In some areas there is a gap between top layer of sensory cells and supporting cells below	1 1/2	Lateral wall consists of simple cuboidal epithelium and medial wall consists of pseudostratified cuboidal epithelium. Walls are of simple cuboidal epithelium		
17 G D		1 1/2		The top row of cells in lateral portion of basal 1/3 of cochlear duct show signs of differentiation into 3 outer and	In basal coil, between inner and outer hair cells, is an area of *highly vacuolated* cytoplasm

	Maculae of utricle and saccule	Number of coils of cochlear duct	Formation of ductus reuniens	Differentiation of inner and outer hair and phalangeal cells	Internal tunnel differentiation
				1 inner hair cells. The hair cells rest on a stratum of supporting cells that has 2 rows of nuclei. The hair cell nuclei stand higher than nuclei of adjacent cells	
18 G. D.		1 3/4 (Full number of coils)	Walls are of simple cuboidal epithelium	Basal and middle coils have inner and outer hair cells. They rest on single layer of supporting cells (phalangeal cells)	Basal and middle coils have area of highly vacuolated cytoplasm in region where internal tunnel is forming
19 G. D.				Basal, middle, and apical coils all have inner and outer hair cells. They rest on a single layer of supporting cells	Basal, middle and apical coils have area of vacuolated cytoplasm in region where tunnel is forming
Notes on subsequent days of development				Next day of significant change is the 8th day postpartum. At that time, inner and outer hair cells are becoming narrower and phalangeal cells are vacuolated. Hair cells and phalangeal cells continue to become narrower on the 9th day. By the 10th day postpartum the hair cells are so narrow that the nucleus occupies the entire width of the cell	By the 10th day postpartum the internal tunnel is mature

Table III

Note. The five following structures do not begin to differentiate before the 17th day of gestation

	Pillar cell differentiation	Space of nuel differentiation	Limbus spiralis differentiation	Sulcus spiralis internus differentiation	Tectorial membrane formation
17 G D					
18 G D			*Limbus is present* in basal coil only Axial portion of caudal wall of basal turn has become simple cuboidal epithelium. Beneath it is cellular condensed connective tissue		
19 G D			Limbus is starting to form in middle coil In basal coil the connective tissue under the epithelium is less *cellular than* on the previous day and there is more extra-cellular matrix		T M begins to form. Represented by *thin strip* of eosinophilic material over the cells in region of sulcus spiralis *internus*
1 P P			Limbus is differentiated throughout the cochlear duct except the ex*treme apex*. In the basal and middle coils there is an area *of low cell* density in the connective tissue immediately under the epithelium		
2 P P				The epithelial cells of the caudal wall of the cochlear duct lateral to the limbus are slightly vacuolated	
3 P P					
4 P P			Limbus is complete throughout the cochlear duct It consists of a mound of con-		

	Pillar cell differentiation	Space of Nuel differentiation	Limbus spiralis differentiation	Sulcus spiralis internus differentiation	Tectorial membrane formation
			nective tissue covered by simple tall cuboidal epithelial cells with long thin nuclei. Beneath the epithelium there is wide band of connective tissue of low cell density		
5 P P	The nuclei of the inner and outer pillar cells have moved to opposite sides of the tunnel				
6 P P				The number of layers of nuclei in basal coil in region of sulcus has decreased to 2 or 3 from original 5. The cytoplasm in this region is disintegrating. Middle coil has 2 to 3 layers of nuclei topped by cytoplasm full of vacuoles	
Notes on subsequent days of development	By the 10th day postpartum the pillar cells attain mature form	On the 9th day postpartum spaces form between phalangeal cells. By 10th day Space of Nuel formed		On 7th day P P the apical coil shows much vacuolization of cytoplasm. Basal and middle coils are similar to previous day On 10th day P P sulcus is complete throughout cochlear duct and is lined by layer of simple cuboidal epithelium	

Table IV

	Stria Vascularis differentiation	Reissner's membrane formation	Formation of Scalae Tympani and Vestibuli
12 G D			Mesenchyme around otocyst is condensed, especially adjacent to ventral portion
13 G D		Rostral wall of cochlear duct consists of epithelium with two to three layers of nuclei	Cochlear duct is completely surrounded by mesenchyme that is more condensed than on the previous day
14 G D		Rostral wall has 2 to 3 layers of nuclei but merges into simple columnar epithelium at the extreme medial and lateral edges of the wall	Connective tissue is differentiated into an inner ring and a denser outer ring
15 G D		Large areas of rostral wall of cochlear duct consist of simple cuboidal epithelium	Outermost ring resembles cartilage. Inner ring is loose connective tissue
16 G D		Rostral wall of cochlear duct consists of simple cuboidal epithelium throughout the duct. This represents the inner cell layer of Reissner's membrane	The connective tissue in the inner ring is very sparse and the cytoplasm of those cells forms fine trabeculae
17 G D	A condensation of mesenchyme containing many capillaries develops adjacent to outer part of rostral wall of cochlear duct. Wall of duct in this region consists of simple cuboidal epithelium		
18 G D	Condensed mesenchyme is denser		Scalae tympani and vestibuli *have formed around basal coil*
19 G D	The condensed mesenchyme is denser. The cuboidal epithelial cells in the part of the wall adjacent to the mesenchyme are smaller and their nuclei are darker staining than in adjacent epithelial cells not developing into stria	Parts of rostral wall of basal turn of cochlear duct have two layers. Inner layer is derived from otocyst, outer layer is from mesenchyme	
1 P P	Boundary between epithelial wall and connective tissue is less distinct. Nuclei of epithelial cells are angular and oriented at a right angle to the connective tissue surface. The epithelial cells are dentate with projections into the connective tissue		
2 P P	No clear boundary is discernible between epithelial wall and condensed connective tissue		Scalae tympani and vestibuli have both reached apex of cochlear duct. Helicotrema not completely formed

	Stria Vascularis differentiation	Reissner' membrane *formation*	Formation of Scalae Tympani and Vestibuli
3 P P	The connective tissue cells are more closely packed and their nuclei are smaller and darker staining than previously	Rostral wall of entire basal and middle coils of cochlear duct consists of two layers of cells	Helicotrema is completed
4 P P	There are 2 limiting walls: outer one is mesenchyme and inner one is from otocyst wall. In between are capillaries intermingled with connective tissue cells	Reissner's membrane is complete in all turns of the cochlear duct	

Table IV

	Stria Vascularis differentiation	Reissner s membrane formation	Formation of Scalae Tympani and Vestibuli
12 G D			Mesenchyme around otocyst is condensed especially adja cent to ventral portion
13 G D		Rostral wall of cochlear duct consists of epithelium with two to three layers of nuclei	Cochlear duct is completely surrounded by mesenchyme that is more condensed than on the previous day
14 G D		Rostral wall has 2 to 3 layers of nuclei but merges into simple columnar epithelium at the extreme medial and lateral edges of the wall	Connective tissue is differentiated into an inner ring and a denser outer ring
15 G D		Large areas of rostral wall of cochlear duct consist of simple cuboidal epithelium	Outermost ring resembles cartilage. Inner ring is loose connective tissue
16 G D		Rostral wall of cochlear duct consists of simple cuboidal epithelium throughout the duct. This represents the inner cell layer of Reissner s membrane	The connective tissue in the inner ring is very sparse and the cytoplasm of those cells forms fine trabeculae
17 G D	A condensation of mesenchyme containing many capillaries develops adjacent to outer part of rostral wall of cochlear duct. Wall of duct in this region consists of simple cuboidal epithelium		
18 G D	Condensed mesenchyme is denser		Scalae tympani and vestibuli have formed around basal coil
19 G D	The condensed mesenchyme is denser The cuboidal epithelial cells in the part of the wall adjacent to the mesenchyme are smaller and their nuclei are darker staining than in adjacent epithelial cells not developing into stria	Parts of rostral wall of basal turn of cochlear duct have two layers. Inner layer is derived from otocyst outer layer is from mesenchyme	
1 P P	Boundary between epithelial wall and connective tissue is less distinct Nuclei of epithelial cells are angular and oriented at a right angle to the connective tissue surface. The epithelial cells are dentate with projections into the connective tissue		
2 P P	No clear boundary is discernible between epithelial wall and condensed connec tive tissue		Scalae tympani and vestibuli have both reached apex of cochlear duct. Helicotrema not completely formed

UPPSALA 1971

Introduction

The basic anatomy of the autonomic innervation of the inner ear is not well understood and is even a matter of considerable dispute. This situation exists in spite of the fact that knowledge of the autonomic innervation patterns could conceivably lead to a better understanding of fundamental influences on the normal hearing process and, thus, to better interpretations of causes underlying some diseases of the inner ear including Ménière's syndrome and some forms of deafness. That at least the sympathetic system might influence the sensory input at the periphery has been indicated by physiological experiments which showed that stimulation of cervical sympathetics results in decreased cochlear microphonics (Seymour & Tappin, 1953) and that transection of fibers of the stellate ganglion results in increased microphonics (Beickert et al. 1956).

Some anatomical support for the physiological findings appeared with the fluorescent results of Spoendlin and Lichtensteiger (1966), who reported that the inner ear was supplied with adrenergic fibers of dual origin and distribution. One group of fibers, according to these observers, formed a perivascular plexus around the labyrinthine artery and its major branches within the modiolus. The other more significant group of fluorescing fibers, distributed with the cochlear nerve fibers rather than with the blood vessels. This latter group of fibers ended in a plexus within the osseous spiral lamina near the habenula perforata, where it was predicated, the norepinephrine released could affect the sensory fibers at the site of the generator potential. Spoendlin (1966) published electron micrographs which supported the finding of such a terminal distribution. Spoendlin & Lichtensteiger (1967) later reported experimental results which indicated that the adrenergic fibers to the inner ear were of dual origin as well as of dual distribution, the perivascular fibers were said to arise from the lower cervical ganglia, the fibers among the acoustic nerve fibers, from the superior cervical ganglion.

The earlier findings of Spoendlin & Lichtensteiger (1966) were quickly opposed by Terayama et al. (1966) who, using essentially the same fluorescent method, found a similar distribution of fluorescent fibers but said that all the fibers were derived from the perivascular plexus and all were related to blood vessels, even those near the habenula. The adrenergic innervation was interpreted by this group of investigators as entirely related to fluid balance. Terayama, working with different collaborators (Terayama et al., 1968), later carried out experiments in which the superior cervical ganglion was extirpated on one side and then, after a time, the inner ears of both sides were examined electron microscopically in order to ascertain localization of degenerating fibers. Results of this study were interpreted as largely confirming the previous findings of Terayama et al. (1966) that the adrenergic system had but one source, the superior cervical ganglion, and that it was almost exclusively related to blood vessels. This new study, however, led to the disclosure that a few fibers with granular vesicles in them were not related to blood vessels. Some of these fibers were found at the habenula and remained normal under the experimental conditions. These fibers were interpreted as belonging largely to the "olivocochlear" bundle.

It was mostly in an attempt to resolve some of the controversy over the source and ultimate distribution of the adrenergic fibers to the inner ear that the present work was begun. Fluorescent results obtained from mouse, rat,

Introduction

The basic anatomy of the autonomic innervation of the inner ear is not well understood and is even a matter of considerable dispute. This situation exists in spite of the fact that knowledge of the autonomic innervation patterns could conceivably lead to a better understanding of fundamental influences on the normal hearing process and, thus, to better interpretations of causes underlying some diseases of the inner ear including Ménière's syndrome and some forms of deafness. That at least the sympathetic system might influence the sensory input at the periphery has been indicated by physiological experiments which showed that stimulation of cervical sympathetics results in decreased cochlear microphonics (Seymour & Tappan 1953) and that transection of fibers of the stellate ganglion results in increased microphonics (Beickert et al. 1956).

Some anatomical support for the physiological findings appeared with the fluorescent results of Spoendlin and Lichtensteiger (1966), who reported that the inner ear was supplied with adrenergic fibers of dual origin and distribution. One group of fibers, according to these observers, formed a perivascular plexus around the labyrinthine artery and its major branches within the modiolus. The other more significant group of fluorescing fibers, distributed with the cochlear nerve fibers rather than with the blood vessels. This latter group of fibers ended in a plexus within the osseous spiral lamina near the habenula perforata, where, it was predicated, the norepinephrine released could affect the sensory fiber at the site of the generator potential. Spoendlin (1966) published electron micrographs which supported the finding of such a terminal distribution. Spoendlin & Lichtensteiger (1967) later reported experimental results which indicated that the adrenergic fibers to the inner ear were of dual origin as well as of dual distribution. the perivascular fibers were said to arise from the lower cervical ganglia, the fibers among the acoustic nerve fibers, from the superior cervical ganglion.

The earlier findings of Spoendlin & Lichtensteiger (1966) were quickly opposed by Terayama et al. (1966) who using essentially the same fluorescent method, found a similar distribution of fluorescent fibers but said that all the fibers were derived from the perivascular plexus and all were related to blood vessels, even those near the habenula. The adrenergic innervation was interpreted by this group of investigators as entirely related to fluid balance. Terayama, working with different collaborators (Terayama et al., 1968), later carried out experiments in which the superior cervical ganglion was extirpated on one side and then after a time, the inner ears of both sides were examined electron microscopically in order to ascertain localization of degenerating fibers. Results of this study were interpreted as largely confirming the previous findings of Terayama et al. (1966) that the adrenergic system had but one source, the superior cervical ganglion, and that it was almost exclusively related to blood vessels. This new study however led to the disclosure that a few fibers with granular vesicles in them were not related to blood vessels. Some of these fibers were found at the habenula and remained normal under the experimental conditions. These fibers were interpreted as belonging largely to the "olivocochlear" bundle.

It was mostly in an attempt to resolve some of the controversy over the source and ultimate distribution of the adrenergic fibers to the inner ear that the present work was begun. Fluorescent results obtained from mouse, rat,

A preliminary report of some of the findings included
here was presented at the meeting of the American
Association of Anatomists in Boston, Massachusetts, April, 1969

Printed in Sweden by
Almqvist & Wiksells Boktryckeri AB
Uppsala 1971

Observations

Fig. 1 is a drawing made from a thick section (1 μ) of the cochlea of the rat stained with toluidine blue and used for orientation purposes for ultra-thin sectioning. This figure should be consulted for localizing the various portions of the cochlea referred to in the text.

Labyrinthine artery

The number of fluorescing fibers along the labyrinthine artery is not great in any of the forms studied (Fig. 2) In the kitten, the fluorescing fibers appear continuous with the perivascular plexus of the basilar-anterior inferior cerebellar arteries. In the mouse and rat this continuity is not so obvious. In the latter forms, the fluorescing fibers along the labyrinthine artery and its major branches appear as the artery positions itself under the eighth nerve the basilar and anterior inferior cerebellar arteries have few fluorescent fibers associated with them.

In the rat and mouse, study of serial sections demonstrates that fluorescing fibers follow a route from the carotid plexus, along the continuation of the internal carotid artery within the skull, through a small foramen into the facial canal, and along the facial nerve from its genu back toward the brain stem. At the internal acoustic meatus, the fibers position themsel es in the arachnoid mater and split into two fascicles which are directed caudally and rostrally around the cochle r nerve The exact further course of these fibers could not be determined conclusively in the fluorescent material the fibers appeared to join the labyrinthine artery and tra el with its main branches, the A estibuli anterior and the A. cochleae communis (terminology followed is that of Smith, 1951)

In all form in est gated, the main branches of the A cochleae communis within the modiolus are supplied with adrenergic fibers as are some eins, especially in the kitten and dog (Fig. 3). In the dog, there are large, green fluorescent structures associated with the smaller arteries located among the branching cochlear nerve fibers (Fig. 4). Whether these are fluorescent cell bodies of neurons, or simply bundles of adrenergic fibers, could not be determined.

The green fluorescent beaded fibers of the perivascular plexuses terminate within the modiolus. Furthermore, in none of the many sections studied have fluorescing fibers been observed diverging from the labyrinthine artery

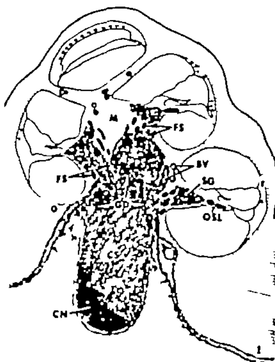

Fig. 1 This drawing, made from a thick (1 μ) section of the rat cochlea used for orientation purposes for lectron microscopy should be consulted for localization of anatomical structures or regions referred to in the text. *BV* blood essels; *CN* cochlear nerve; *CS*, central segment of the cochlear nerve; *FS*, foramina of the spiral tract; *GD* glial dome of the cochlear nerve, separating central and peripheral segments of the nerve; *M* modiolar bone; *OSL*, osseous spiral lamina; *FS*, peripheral segment of the cochlear nerve; *SG* spiral ganglion.

cat and puppy form the main basis of the report presented here Most recently investigation of the localization of unmyelinated fibers in various portions of the inner ears of these same forms at the level of the electron microscope has been initiated in order to better determine the relationship of such fibers to the vascular system. Although the latter work, when completed will be published separately pertinent data already obtained from one form, the rat is included here.

Materials and Methods

This report is based upon fluorescence microscopic investigations of serial sections obtained from 28 mice and 45 albino rats (Sprague Dawley) ranging in age from 17–26 days and 10 kittens and 1 puppy which were newborn. Electron microscopic examination of cochleae from 13 rats ranging from 17 days to 2 months in age was also carried out. The complete technique used in preparing the tissue for fluorescence microscopy has been published elsewhere (Ross, 1969 *b*) Briefly all animals were decapitated and after removal of lower jaw fur and extraneous tissue the head with inner ears *in situ* was quick frozen on dry ice while being sprayed with Cryokwik (International Equipment Company) The tissue was mounted and sectioned at 14 μ in a cryostat at 20 C and serial sections were mounted on warm slides. All sections were stored in the cryostat in glass staining dishes containing a little silica gel and when sectioning was completed, were allowed to dry in the cryostat overnight (about 16 hours) with the anti fog fan running In the morning the slides were transferred to Coplin jars filled to one third capacity with paraformaldehyde which had been previously stored over 54% sulfuric acid The jars were sealed and placed in an 80 C oven for periods ranging from 15 min to 3 hours, with 1 hour incubation time the usual case. Sections were allowed to cool then mounted in immersion oil and studied with a Leitz Ortholux fluorescent microscope. A 2 mm KG 1 heat filter and a 3 mm UG 1 filter were used as excitation filters Barrier filters of 510 and 530 nm were employed and dark field illumination was used exclusively All photomicrographs shown here were taken using the 530 nm barrier filter on TRI X Pan Film (Kodak) utilizing 1 $^{1}/_{2}$ min exposure time.

Eleven of the rats prepared for electron microscopy were anesthetized with chloral hydrate (1 ml/100 g body weight) injected intraperitoneally and then perfused for about 20 min with glutaraldehyde-paraformaldehyde (Karnovsky 1965) in 0.2 M sodium-cacodylate HCl buffer Entire cochleae were removed and placed in ethylenedinitrilotetraacetic acid glutaraldehyde (Baird et al 1967) for 3 weeks for decalcification Tissues were post fixed in 1% OsO_4 in 0 144 M sodium-cacodylate HCl buffer to which 0 15 CaCl had been added, dehydrated in a graded series of alcohols, and embedded in Epon The remaining 2 rats used for electron microscopy were prepared in a similar way except that a Krebs Ringer phosphate buffer (Van Orden et al 1970) was substituted for the cacodylate buffer This procedure was followed in the hope of preserving membrane bound granules in the adrenergic fibers. Sections 1–2 μ thick were cut and stained with toluidine blue for orientation purposes, after which the block was trimmed and ultra-thin sections were cut Sections were mounted unsupported on 200 mesh grids or on single hole grids covered with Formvar membranes stained with lead citrate (Reynolds, 1963), and studied on a RCA EMU 3 G electron microscope.

Observations

Fig. 1 is a drawing made from a thick section (1 μ) of the cochlea of the rat stained with toluidine blue and used for orientation purposes for ultra-thin sectioning. This figure should be consulted for localizing the various portions of the cochlea referred to in the text.

Labyrinthine artery

The number of fluorescing fibers along the labyrinthine artery is not great in any of the forms studied (Fig.) In the kitten, the fluorescing fibers appear continuous with the perivascular plexus of the basilar-anterior inferior cerebellar arteries. In the mouse and rat this continuity is not so obvious. In the latter forms, the fluorescing fibers along the labyrinthine artery and its major branches appear as the artery positions itself under the eighth nerve the basilar and anterior inferior cerebellar arteries have few fluorescent fibers associated with them.

In the rat and mouse, study of serial sections demonstrates that fluorescing fibers follow a route from the carotid plexus, along the continuation of the internal carotid artery within the skull, through a small foramen into the facial canal, and along the facial nerve from its genu back toward the brain stem. At the internal acoustic meatus, the fibers position themselves in the arachnoid mater and split into two fascicles which are directed caudally and rostrally around the cochlear nerve. The exact further course of these fibers could not be determined conclusively in the fluorescent material; the fibers appeared to join the labyrinthine artery and travel with its main branches, the A. vestibuli anterior and the A. cochleae communis (terminology followed is that of Smith, 1951).

In all forms investigated, the main branches of the A. cochleae communis within the modiolus are supplied with adrenergic fibers as are some veins, especially in the kitten and dog (Fig. 3). In the dog, there are large, green fluorescent structures associated with the smaller arteries located among the branching cochlear nerve fibers (Fig. 4). Whether these are fluorescent cell bodies of neurons, or simply bundles of adrenergic fibers, could not be determined.

The green fluorescent beaded fibers of the perivascular plexuses terminate within the modiolus. Furthermore, in none of the many sections studied have fluorescing fibers been observed diverging from the labyrinthine artery

This report is based upon fluorescence microscopic investigations of serial sections obtained from 28 mice and 45 albino rats (Sprague Dawley) ranging in age from 17–26 days and 10 kittens and 1 puppy which were newborn Electron microscopic examination of cochleae from 13 rats ranging from 17 days to 2 months in age was also carried out The complete technique used in preparing the tissue for fluorescence microscopy has been published elsewhere (Ross 1969 *b*) Briefly all animals were decapitated and after removal of lower jaw fur and extraneous tissue the head with inner ears *in situ* was quick frozen on dry ice while being sprayed with Cryokwik (International Equipment Company) The tissue was mounted and sectioned at 14 μ in a cryostat at 20 C and serial sections were mounted on warm slides. All sections were stored in the cryostat in glass staining dishes containing a little silica gel and when sectioning was completed were allowed to dry in the cryostat overnight (about 16 hours) with the anti fog fan running In the morning the slides were transferred to Coplin jars filled to one third capacity with paraformaldehyde which had been previously stored over 54% sulfuric acid. The jars were sealed and placed in an 80 C oven for periods ranging from 15 min to 3 hours, with 1 hour incubation time the usual case. Sections were allowed to cool, then mounted in immersion oil and studied with a Leitz Ortholux fluorescent microscope A 2 mm KG 1 heat filter and a 3 mm UG 1 filter were used as excitation filters. Barrier filters of 510 and 530 nm were employed, and dark field illumination was used exclusively All photomicrographs shown here were taken using the 530 nm barrier filter on TRI X Pan Film (Kodak) utilizing 1 $^1/_2$ min exposure time.

Eleven of the rats prepared for electron microscopy were anesthetized with chloral hydrate (1 ml/100 g body weight) injected intraperitoneally and then perfused for about 20 min with glutaraldehyde paraformaldehyde (Karnovsky 1965) in 0 2 M sodium-cacodylate HCl buffer Entire cochleae were removed and placed in ethylenedinitrilotetraacetic acid-glutaraldehyde (Baird et al. 1967) for 3 weeks for decalcification Tissues were post fixed in 1% OsO_4 in 0 144 M sodium-cacodylate HCl buffer to which 0 15 CaCl had been added dehydrated in a graded series of alcohols, and embedded in Epon The remaining 2 rats used for electron microscopy were prepared in a similar way except that a Krebs Ringer phosphate buffer (Van Orden et al. 1970) was substituted for the cacodylate buffer This procedure was followed in the hope of preserving membrane-bound granules in the adrenergic fibers. Sections 1–2 μ thick were cut and stained with toluidine blue for orientation purposes after which the block was trimmed and ultra thin sections were cut Sections were mounted unsupported on 200 mesh grids or on single hole grids covered with Formvar membranes, stained with lead citrate (Reynolds, 1963) and studied on a RCA EMU 3 G electron microscope.

Observations

Fig. 1 is a drawing made from a thick section (1 μ) of the cochlea of the rat stained with toluidine blue and used for orientation purposes for ultra-thin sectioning. This figure should be consulted for localizing the various portions of the cochlea referred to in the text.

Labyrinthine artery

The number of fluorescing fibers along the labyrinthine artery is not great in any of the forms studied (Fig. 2). In the kitten, the fluorescing fibers appear continuous with the perivascular plexus of the basilar-anterior inferior cerebellar arteries. In the mouse and rat this continuity is not so obvious. In the latter forms, the fluorescing fibers along the labyrinthine artery and its major branches appear as the artery positions itself under the eighth nerve; the basilar and anterior inferior cerebellar arteries have few fluorescent fibers associated with them.

In the rat and mouse, study of serial sections demonstrates that fluorescing fibers follow a route from the carotid plexus, along the continuation of the internal carotid artery within the skull, through a small foramen into the facial canal, and along the facial nerve from its genu back toward the brain stem. At the internal acoustic meatus, the fibers position themselves in the arachnoid mater and split into two fascicles which are directed caudally and rostrally around the cochlear nerve. The exact further course of these fibers could not be determined conclusively in the fluorescent material; the fibers appeared to join the labyrinthine artery and travel with its main branches, the A. vestibuli anterior and the A. cochleae communis (terminology followed is that of Smith, 1951).

In all forms investigated, the main branches of the A. cochleae communis within the modiolus are supplied with adrenergic fibers as are some veins, especially in the kitten and dog (Fig. 3). In the dog, there are large, green fluorescent structures associated with the smaller arteries located among the branching cochlear nerve fibers (Fig. 4). Whether these are fluorescent cell bodies of neurons, or simply bundles of adrenergic fibers, could not be determined.

The green fluorescent beaded fibers of the perivascular plexuses terminate within the modiolus. Furthermore, in none of the many sections studied have fluorescing fibers been observed diverging from the labyrinthine artery

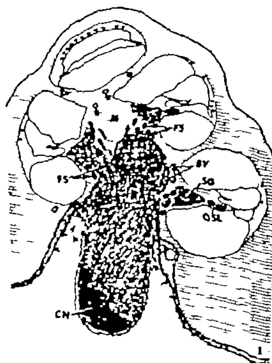

Fig. 1. This drawing, made from a thick (1 μ) sectio[n] of the rat cochlea used for orientation purposes f[or] electron microscopy, should be consulted for localiz[a]tion of anatomical structures or regions referred to [in] the text. *BV*, blood vessels; *CN*, cochlear nerve; *C*[...] central segment of the cochlear nerve; *FS*, foramin[a] of the spiral tract; *GD*, glial dome of the cochle[ar] nerve, separating central and peripheral segments [of] the nerve; *M*, modiolar bone; *OSL*, osseous spi[ral] lamina; *PS*, peripheral segment of the cochlear nerv[e]; *SG*, spiral ganglion.

cat and puppy form the main basis of the report presented here. Most recently investigation of the localization of unmyelinated fibers in various portions of the inner ears of these same forms at the level of the electron microscope has been initiated in order to better determine the relationship of such fibers to the vascular system. Although the latter work, when completed will be published separately pertinent data already obtained from one form, the rat, is included here

Materials and Methods

This report is based upon fluorescence microscopic investigations of serial sections obtained from 28 mice and 45 albino rats (Sprague Dawley) ranging in age from 17–26 days and 10 kittens and 1 puppy which were newborn Electron microscopic examination of cochleae from 13 rats ranging from 17 days to 2 months in age was also carried out. The complete technique used in preparing the tissue for fluorescence microscopy has been published elsewhere (Ross, 1969 *b*) Briefly all animals were decapitated and, after removal of lower jaw fur and extraneous tissue the head with inner ears *in situ* was quick frozen on dry ice while being sprayed with Cryokwik (International Equipment Company) The tissue was mounted and sectioned at 14 μ in a cryostat at -20 C and serial sections were mounted on warm slides. All sections were stored in the cryostat in glass staining dishes containing a little silica gel and when sectioning was completed were allowed to dry in the cryostat overnight (about 16 hours) with the anti fog fan running In the morning the slides were transferred to Coplin jars filled to one third capacity with paraformaldehyde which had been previously stored over 54% sulfuric acid The jars were sealed and placed in an 80 C oven for periods ranging from 15 min to 3 hours with 1 hour incubation time the usual case Sections were allowed to cool then mounted in immersion oil and studied with a Leitz Ortholux fluorescent microscope. A 2 mm KG 1 heat filter and a 3 mm UG 1 filter were used as excitation filters. Barrier filters of 510 and 530 nm were employed and dark field illumination was used exclusively All photomicrographs shown here were taken using the 530 nm barrier filter on TRI X Pan Film (Kodak) utilizing 1 1/2 min exposure time

Eleven of the rats prepared for electron microscopy were anesthetized with chloral hydrate (1 ml/100 g body weight) injected intraperitoneally and then perfused for about 20 min with glutaraldehyde paraformaldehyde (Karnovsky 1965) in 0.2 M sodium-cacodylate HCl buffer Entire cochleae were removed and placed in ethylenedinitrilotetraacetic acid glutaraldehyde (Baird et al 1967) for 3 weeks for decalcification. Tissues were post fixed in 1% OsO_4 in 0 144 M sodium-cacodylate HCl buffer to which 0 15 CaCl had been added dehydrated in a graded series of alcohols, and embedded in Epon. The remaining 2 rats used for electron microscopy were prepared in a similar way except that a Krebs Ringer-phosphate buffer (Van Orden et al., 1970) was substituted for the cacodylate buffer This procedure was followed in the hope of preserving membrane-bound granules in the adrenergic fibers. Sections 1–2 μ thick were cut and stained with toluidine blue for orientation purposes, after which the block was trimmed and ultra thin sections were cut. Sections were mounted unsupported on 200 mesh grids or on single hole grids covered with Formvar membranes, stained with lead citrate (Reynolds, 1963) and studied on a RCA EMU 3 G electron microscope.

Observations

Fig. 1 is a drawing made from a thick section (1 μ) of the cochlea of the rat stained with toluidine blue and used for orientation purposes for ultra-thin sectioning. This figure should be consulted for localizing the various *portions of the* cochlea referred to in the text.

Labyrinthine artery

The number of fluorescing fibers along the labyrinthine artery is not great in any of the forms studied (Fig. 2). In the kitten, the fluorescing fibers appear continuous with the perivascular plexus of the basilar-anterior inferior cerebellar arteries. In the mouse and rat this continuity is not so obvious. In the latter forms, the fluorescing fibers along the labyrinthine artery and its major branches appear as the artery positions itself under the eighth nerve; the basilar and anterior inferior cerebellar arteries have few fluorescent fibers associated with them.

In the rat and mouse, study of serial sections demonstrates that fluorescing fibers follow a route from the carotid plexus, along the continuation of the internal carotid artery within the skull, through a small foramen into the facial canal, and along the facial nerve from its genu back toward the brain stem. At the internal acoustic meatus, the fibers position themselves in the arachnoid mater and split into two fascicles which are directed caudally and rostrally around the cochlear nerve. The exact further course of these fibers could not be determined conclusively in the fluorescent material; the fibers appeared to join the labyrinthine artery and travel with its main branches, the A. vestibuli anterior and the A. cochleae communis (terminology followed is that of Smith, 1951).

In all forms investigated, the main branches of the A. cochleae communis within the modiolus are supplied with adrenergic fibers as are some veins, especially in the kitten and dog (Fig. 3). In the dog, there are large, green fluorescent structures associated with the smaller arteries located among the branching cochlear nerve fibers (Fig. 4). Whether these are fluorescent cell bodies of neurons, or simply bundles of adrenergic fibers, could not be determined.

The green fluorescent beaded fibers of the perivascular plexuses terminate within the modiolus. Furthermore, in none of the many sections studied have fluorescing fibers been observed diverging from the labyrinthine artery

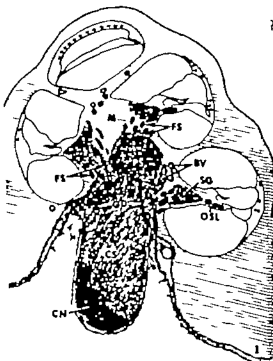

Fig. 1. This drawing, made from a thick (1 μ) section of the rat cochlea used for orientation purposes for electron microscopy, should be consulted for localization of anatomical structures or regions referred to in the text. *BV*, blood vessels; *CN*, cochlear nerve; *CS*, central segment of the cochlear nerve; *FS*, foramina of the spiral tract; *GD*, glial dome of the cochlear nerve, separating central and peripheral segments of the nerve; *M*, modiolar bone; *OSL*, osseous spiral lamina; *PS*, peripheral segment of the cochlear nerve; *SG*, spiral ganglion.

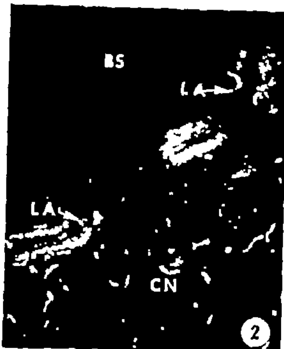

Fig 2 Labyrinthine artery kitten. Only a few fluorescent fibers are associated with the labyrinthine artery which has thin walls The artery (*LA*) is shown here as it curves between the brain stem (*BS*) and cochlear nerve (*CN*) which contains fluorescent fibers. 120
Fig 3 Branches of the spiral modiolar artery (single arrow) and vein (double arrows) dog Fluorescent fibers are associated with both arterial and venous spiral modiolar vessels in all forms studied but are most numerous in the dog. × 120
Fig 4 Spiral modiolar artery proximal to the vessel shown in Fig. 3 Fluorescent structures (arrows) occur along the larger arterial branches to the inner ear in the dog. Whether these structures are small, fluorescent cells or simply bundles of fluorescing fibers could not be determined in the present material. 120
Fig 5 Fluorescent fibers of the cochlear nerve, kitten. The fluorescent fibers appear abruptly in the peripheral segment (*PS*) of the cochlear nerve immediately distal to the glial dome (arrows) The central segment of the cochlear nerve (*CS*) contains only a few scattered, fluorescent structures. 116

or its branches to enter the substance of the cochlear nerve Thus, the perivascular plexus associated with the major cochlear vessels appears to be separate from the adrenergic system of fibers running within the cochlear nerve.

Cochlear nerve

A marked difference in background fluorescence exists between the *central* and *peripheral segments* of the acoustic nerve in the forms studied, so that the glial dome is sharply demarcated (Fig. 5). The perikarya of neurons of the acoustic nerve nucleus, with associated *orange* or *green fluorescence*, lie central to the dome in the mouse and rat (Ross, 1969 *b*). In the kitten, a few fine fluorescent beaded fibers and scattered fluorescent granules occur in the central segment. Observations on the central portion of the acoustic nerve of the dog have been too limited to present an adequate description of fluorescence.

In all cases, green fluorescing fibers, often in thick bundles, appear abruptly at the glial dome running in the peripheral segment of the cochlear nerve. The bundles of fluorescing fibers course peripheralward, joining the fascicles of acoustic nerve fibers at the foramina of the spiral tract (Fig. 6). They enter the *foramina* and continue peripheralward to Rosenthal's canal. At the light microscope level, the fibers appear to be intermingled with acoustic nerve fibers and not particularly related to blood vessels.

Electron microscopic observations of this same portion of the acoustic nerve indicate that all of the blood vessels within the nerve are capillaries or postcapillary venules, containing no smooth muscle in their walls. The capillaries have been classified according to the criteria presented by Rhodin (1968) as venous or arterial in the accompanying micrographs. None of the capillaries are fenestrated. The vessels are enclosed by perivascular sheaths of pia-like cells in which occasional openings occur (Fig. 7).

Proximal to the foramina of the spiral tract, unmyelinated fibers run among acoustic nerve fibers or within a few micra of the perivascular sheaths (Fig. 7). All the unmyelinated fibers observed have been enclosed to some degree in Schwann cell cytoplasm and are never intimately associated with the cells of the perivascular sheath or with the endothelial cells of the capillaries. Within the foramina of the spiral tract, the bundles of acoustic nerve fibers are frequently devoid of capillaries. Unmyelinated fibers occur intermingled with the myelinated in these bundles.

Spiral canal

The green fluorescing beaded fibers, some still in small bundles, interweave in part in a plexus immediately proximal to the spiral ganglion cells. Although some fibers cross the spiral ganglion to reach the intraganglionic spiral bundle and the root of the osseous spiral lamina in all the forms studied (Figs. 8 and 9), such crossing fibers are most numerous in the rat and mouse. In the kitten, many of the fibers travel around the ganglion by passing close to the bony walls of the spiral canal and then run toward the root of the osseous spiral lamina. On rare occasion, some of the crossing fibers become closely associated with, or appear to partly coil about, the perikarya of spiral ganglion cells (Fig. 9). No fluorescent perikarya have been observed in the spiral ganglion of any form studied.

Electron microscopy confirms the fact that unmyelinated fibers are abundant between the spiral ganglion cells but are infrequently situated near the capillaries or postcapillary venules (Fig. 10). The vessels are again enclosed by perivascular sheaths which are, however, usually incomplete.

Osseous spiral lamina

A plexus of fluorescent fibers occurs at the root of the osseous spiral lamina (Fig. 11) in the region of the intraganglionic spiral bundle. In the rat and mouse *particularly some* of the fluorescing fibers run with the latter bundle. In horizontal sections, the *fluorescent fibers* project peripheralward in closely parallel array (Figs. 11 and 12) and *form a plexus* with arcades (Fig. 12) in the region of the inner spiral vessel. When viewed in vertical sections, the *fluorescent fibers* course predominantly along the tympanic *face of the* lamina near the inner spiral vessel and also along the upper

The arrows indicate the terminal beads of single fibers in the foramina nervosa. Portions of the spiral limbus (*SL*) are autofluorescent. ×120.

Fig. 14. Slightly oblique section through the habenula perforata, middle third of the cochlea, kitten. Several terminal beads, each in a foramen nervosum, occur between the arrows. Each foramen appears to receive a single terminal. The arrow heads indicate some of the fluorescent fibers, usually in small fascicles, of the peripheral plexus in the osseous spiral lamina. (*SL*, spiral limbus.) ×170.

plate of bone where capillaries course (Fig. 13). A plexus with arcades connects the fluorescing fibers in the region of the inner spiral vessel. Additionally, in the present fluorescent material, there are fibers which terminate as end beads in the foramina nervosa (Figs. 13 and 14). These terminals are most conspicuous in the kitten. None of the green fluorescent fibers have been traced into the organ of Corti. The general pattern of distribution of the fluorescent, adrenergic fibers appeared to be similar in all turns of the cochlea in the species studied.

Examination of sections from the rat osseous spiral lamina with the electron microscope shows that unmyelinated fibers increase tremendously in number at the root of the osseous spiral lamina (Fig. 15), where they course, for the most part, in the intraganglionic spiral bundle. The latter bundle consists of unmyelinated, thinly myelinated, and thickly myelinated fibers. Many of the unmyelinated fibers presumably end within the bundle. This assumption is based upon the fact that the more peripherally coursing bundles of acoustic nerve fibers contain fewer unmyelinated fibers than would be expected on the basis of the numbers present at the root.

Blood vessels with thin walls and an incomplete investment of pericytes cross the region of the intraganglionic spiral bundle at the root of the osseous spiral lamina as they travel toward the modiolar bone. These vessels, on the basis of the ultrastructure of their walls, might be classified as venous capillaries (*Rhodin, 1968*). However, on the basis of their location and large size the vessels correspond to postcapillary venules. The dilated portions ("beads") of beaded, unmyelinated fibers sometimes are associated with these vessels (Fig. 16).

The acoustic nerve fibers traverse the osseous spiral lamina in bundles which run between bony trabeculae. The bundles themselves are devoid of capillaries and are comprised of myelinated nerve fibers, some unmyelinated

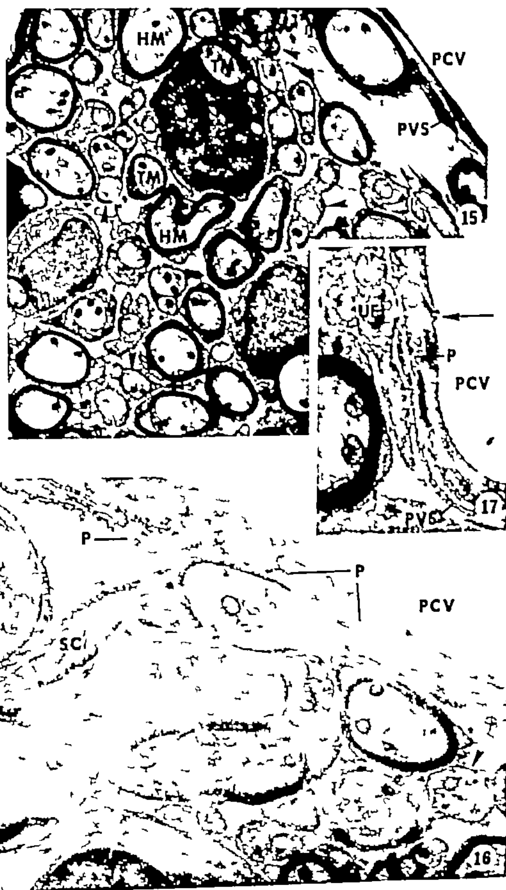
fibers, and Schwann cells. In the better preserved material extracellular space diminishes and becomes minimal most peripheralward. Collagen fibrils occur in the narrow extracellular spaces.

The unmyelinated fibers are located among the myelinated fibers or at the periphery of the bundles of nerve fibers. Those fibers at the periphery are sometimes closely related to the perivascular sheaths of the postcapillary venules or venous capillaries which run between the nerve bundles. Rarely unmyelinated fibers have been observed lying within 750–1 000 Å of cell membranes of pericytes of postcapillary venules traveling between the nerve bundles. In one such case, the perivascular sheath was not present and the Schwann cell covering was attenuated (Fig 17).

The blood vessels will be described elsewhere in greater detail, however it should be stressed here that, in the rat at least, none of the vessels in the osseous spiral lamina possess smooth muscle in their walls. All of them are either capillaries or postcapillary venules.

Discussion



Anatomical results of the present study are in general agreement with the previously published findings of Spoendlin (1966) and Spoendlin & Lichtensteiger (1966, 1967). In concurrence with these authors and in contrast to the findings of Terayama et al. (1966, 1968), there appears to be a dual distribution of adrenergic fibers in the inner ear: one group of fibers is perivascular and the other usually courses independently of blood vessels among acoustic nerve fibers.

It has not been possible in the present anatomical material to establish conclusively whether or not the two groups of fibers are of entirely separate origins. Some adrenergic fibers reach the labyrinthine artery from the basilar plexus, in the rat and mouse, this contribution appears to be minor. A second, more significant, group of fluorescent fibers reaches the inner ear by way of a facial anastomosis. The route taken by this group of fibers is from the carotid plexus to the facial nerve along a course corresponding to that of the greater superficial petrosal nerve then along the facial nerve to the arachnoid mater near the cochlear nerve. This connection could be traced in its entirety in fluorescent material only in the rat and mouse and, in these forms, the further course of the fibers appeared to be along the labyrinthine artery. However, some of the fibers may have turned into the peripheral segments of the acoustic or vestibular nerves.

Fig 15 Cross section of the intraganglionic spiral bundle, middle third of the cochlea, rat. This electron micrograph demonstrates the fact that the intraganglionic spiral bundle contains unmyelinated (arrow heads), thinly myelinated (*TM*), and heavily myelinated (*HM*) nerve fibers. The blood vessel (*PCV*) appears to be a postcapillary venule. (*PVS* perivascular sheath.) 3 900.

Fig 16 An electron micrograph of an unmyelinated fiber lying close to the wall of a postcapillary venule (*PCV*), middle third of the cochlea, rat. Although the unmyelinated fiber is sectioned through an enlargement, or "bead" the Schwann cell (*SC*) still completely envelops the fiber. The sheaths of other unmyelinated fibers (arrow heads at lower right), located farther from the postcapillary venule, are either attenuated or lacking. (*P* pericyte.) 12 600.

Fig 17 Unmyelinated fiber close to the pericyte of the wall of a postcapillary venule in the osseous spiral lamina, middle third of the cochlea, rat. In this instance, a small fascicle of unmyelinated fibers approaches the outer cell membrane of a pericyte (*P*). The unmyelinated fiber (*UF*) closest to the membrane of the pericyte (*P*) has an attenuated Schwann cell covering; no perivascular sheath (*PVS*) intervenes. Overlap of the endothelial cells of the postcapillary venule (*PCV*) is indicated by the arrow. 5 800.

However some of the fibers may have turned into the peripheral segments of the acoustic or vestibular nerves.

Fig 15 Cross section of the intraganglionic spiral bundle, middle third of the cochlea, rat. This electron micrograph demonstrates the fact that the intraganglionic spiral bundle contains unmyelinated (arrow heads), thinly myelinated (*TM*), and heavily myelinated (*HM*) nerve fibers. The blood vessel (*PCV*) appears to be postcapillary venule. (*PVS* perivascular sheath.) 3 900.

Fig 16 An electron micrograph of an unmyelinated fiber lying close to the wall of a postcapillary venule (*PCV*), middle third of the cochlea, rat. Although the unmyelinated fiber is sectioned through an enlargement, or "bead" the Schwann cell (*SC*) still completely envelops the fiber. The sheaths of other unmyelinated fibers (arrow heads at lower right), located farther from the postcapillary venule, are either attenuated or lacking. (*P* pericyte.) 1 600.

Fig. 1 Unmyelinated fiber close to the pericyte of the wall of a postcapillary venule in the osseous spiral lamina, middle third of the cochlea, rat. In this instance, small fascicle of unmyelinated fibers approaches the outer cell membrane of a pericyte (*P*). The unmyelinated fiber (*UF*) closest to the membrane of the pericyte (*P*) has an attenuated Schwann cell covering; no perivascular sheath (*PVS*) intervenes. Overlap of the endothelial cells of the postcapillary venule (*PCV*) is indicated by the arrow 5 800.

the *inner ear* indicating that they are concerned with a general rather than a specific and highly localized function. However the exact nature of this *generalized function* remains to be physiologically elucidated for the inner ear. Terayama et al. (1966, *1968*) and Spoendlin & *Lichtensteiger* (1966), *observing essentially the same* adrenergic plexus in the inner ear reached entirely different conclusions concerning its functional significance, as has already been pointed out. However both conclusions may be partially correct.

With the finding that fluorescent terminals extend into the *foramina nervosa*, the possibility that the *adrenergic system can influence acoustic nerve* activity at the site of generation of the action potential as predicated by Spoendlin & Lichtensteiger (1966) is on firm anatomical ground. Whether this effect is facilitatory or inhibitory can only be speculated upon in the absence of physiological or pharmacological data. *In the case of* Pacinian corpuscles, where fluorescent fibers have been observed (Santini, 1969) and where primary catecholamines ha e *been shown* to occur (Chunchkov 1968), topical application of norepinephrine or epinephrine results in enhancement of response of the receptor to stimulation (Loewenstein & Altamirano-Orrego 1956). Chernetski (1964) has found that sympathetic stimulation enhances peripheral sensory afferent activity in the frog and has hypothesized that a vertebrate arousal system dependent upon sympathetic outflow *may* exist. Thus, previous experimental results point to the possibility *of enhancement of auditory* nerve activity by the adrenergic nervous system.

However the fibers projecting into the foramina nervosa, demonstrated by fluorescent microscopy here for the first time, represent only a portion of the *adrenergic plexus* in the osseous spiral lamina. The *remaining fibers*, which form arcades and lie below those to the foramina, are the fibers actually described in the prior reports of both Spoendlin & Lichtensteiger (1966, *1967*) and Terayama et al. (1966). These latter fibers are considered here to be possibly related to regulating *fluid* balance within the cochlea. *Although this* interpretation is *in partial agreement* with Terayama et al. (1966, 1968), present conclusions differ in salient respects from theirs.

The anatomical evidence suggests that the adrenergic regulation of fluid balance in the cochlea is achieved in a two-fold way: (1) by regulation of total blood flow into the cochlea through the sympathetic innervation of the labyrinthine artery and *its major branches* within the *modiolus*, and (2) by *regulation of fluid* balance between the intra and extravascular fluids through the peripheral vascular bed. Functionally related to the latter control is the adrenergic innervation of the larger veins leaving the modiolus.

The *peripheral regulatory effects of nor*epinephrine would appear to be of far greater significance to *inner ear function* than the *adrenergic control* of the *labyrinthine artery* when the great numbers of fluorescing fibers extending radialward in the osseous spiral lamina are compared with the small numbers of fluorescing fibers along the artery. Although electron microscopic studies indicate that some of the unmyelinated fibers in the nerve bundles of the osseous spiral lamina may lie within 750–1 000 Å *of pericytes or* perivascular sheaths of postcapillary venules, *most of these* fibers course among the myelinated fibers of the bundles. Thus, release of norepinephrine can occur some distance from the capillary bed into the surrounding tissue fluid. Acoustic nerve fibers, capillaries, and even the perikarya *of the spiral ganglion* may at time, or always, exist and function *in a milieu* rich in norepinephrine.

No close apposition (200 Å) of unmyelinated fibers with endothelial cells of capillaries, as reported by Terayama et al. (1968) to occur in the guinea pig, has been observed in the rat. This could be due to species variation.

The actual *site or sites* in the inner ear which are under the *influence* of norepinephrine can only be determined *experimentally*

Spoendlin & Lichtensteiger (1967) working with cats, have presented experimental evidence that this group of fibers distributes among the acoustic nerve fibers.

The connection from the pericarotid plexus to the facial nerve by way of the greater superficial petrosal nerve as described here on the basis of fluorescent results, was known to earlier anatomists (Pleschel, 1844 in horse Arnold, 1851 in man and calf Henle 1872, in man Penzo 1893 in man cat rat mouse and several other forms Rauber & Kopsch 1909 in man and others) More recently it was described by Chorobski & Penfield (1932, in monkey and man) who found that at least part of the fibers of the anastomosis were parasympathetic and were directed from nervus intermedius to the carotid plexus Some of the earlier investigators indicated that this connection carried sympathetic fibers back toward the facial nerve (Arnold, 1851 Penzo 1893 and others) Arnold and Penzo described the further course of the sympathetic fibers as along the facial nerve back toward the internal acoustic meatus and into the vestibular division of the eighth cranial nerve That the last named authors did not confuse the sympathetic anastomosis with known connections of nervus intermedius appears certain for they also described direct motor fibers of nervus intermedius into the greater superficial petrosal nerve and an anastomosis of nervus intermedius with the vestibular nerve

Thus, early and more recent results (Spoendlin & Lichtensteiger 1967) as well as the present fluorescent findings, indicate that the carotid plexus makes an important communication with the inner ear structures by way of a facial anastomosis. The course taken by the fibers to the facial nerve is probably subject to individual variation Spoendlin & Lichtensteiger (1967) indicated that in the cats used in their studies, the carotid plexus was linked to the seventh cranial nerve by anastomoses with the tenth cranial nerve or with the tympanic plexus.

An interesting difference between the rodents and the other forms used in this study has been the presence of fluorescing multipolar neurons in the central segment of the cochlear nerve in the rodent The histochemical and ultrastructural properties of these neurons have been published (Ross, 1969 b Ross & Burkel, 1970) and will not be taken up again here However these neurons resemble autonomic cells in many ways and it is possible that in the rodent they contribute to the adrenergic innervation of the inner ear

The distribution of the cochlear adrenergic fibers is among ordinary acoustic nerve fibers and spiral ganglion cells almost exclusively according to present fluorescent and electron microscopic findings. These results concur with those of Spoendlin & Lichtensteiger (1966) but are in disagreement with Terayama et al (1966 1968)

The presence of unmyelinated or fluorescent fibers among myelinated nerve fibers in nerve roots or among the perikarya of neurons in sensory ganglia is not peculiar to the acoustic nerve and its ganglion A similar distribution occurs in the vestibular ganglion (personal observations) and has been reported for the fifth cranial nerve and its ganglion in the cat after fluorescent studies (Santini 1966) and electron microscopic investigations (Dixon, 1963) Fluorescent fibers have also been observed in the cat dorsal root ganglion (Owman & Santini, 1966) and rat ventral roots (Dahlström & Fuxe 1965) Occasionally the fluorescent fibers of the Gasserian ganglion and of the dorsal root ganglia were found to coil about the neuronal perikarya as was observed here in the case of the spiral ganglia The possibility exists that the acetylcholinesterase positive fibers observed coiling about spiral ganglion cells previously (Ross 1969 a) might also be adrenergic Numerous recent studies have shown that acetylcholinesterase is associated in varying amounts with a wide variety of both sensory and motor neurons (see Nachmansohn 1970 for review)

The fluorescent adrenergic fibers interweave extensively as they course peripheralward in

the inner ear indicating that they are concerned with a general rather than a specific and highly localized function. However the exact nature of this generalized function remains to be physiologically elucidated for the inner ear. Terayama et al. (1966, 1968) and Spoendlin & Lichtensteiger (1966), observing essentially the same adrenergic plexus in the inner ear reached entirely different conclusions concerning its functional significance, as has already been pointed out. However both conclusions may be partially correct.

With the finding that fluorescent terminals extend into the foramina nervosa, the possibility that the adrenergic system can influence acoustic nerve activity *at the site of generation* of the action potential as predicated by Spoendlin & Lichtensteiger (1966) is on firm anatomical ground. Whether this effect is facilitatory or inhibitory can only be speculated upon in the absence of physiological or pharmacological data. In the case of Pacinian corpuscles, *where fluorescent fibers have been* observed (Santini, 1969) and where primary catecholamines have been shown to occur (Chouchkov 1968), topical application of norepinephrine or epinephrine results in enhancement of response of the receptor to stimulation (Loewenstein & Altamirano-Orrego, 1956). Chernetski (1964) has found that sympathetic stimulation enhances peripheral sensory afferent activity in the frog and has hypothesized that a vertebrate arousal system dependent upon sympathetic outflow may exist. Thus, previous experimental results point to the possibility of enhancement of auditory nerve activity by the adrenergic nervous system.

However the fibers projecting into the foramina nervosa, demonstrated by fluorescent microscopy here for the first time, represent only a portion of the adrenergic plexus in the osseous spiral lamina. The remaining fibers, which form arcades and lie below those to the foramina, are the fibers actually described in the prior reports of both Spoendlin & Lichtensteiger (1966, 1967) and Terayama et al. (1966). These latter fibers are considered here to be possibly related to regulating fluid balance within the cochlea. Although this interpretation is in partial agreement with Terayama et al. (1966, 1968), present conclusions differ in salient respects from theirs.

The anatomical evidence suggests that the adrenergic regulation of fluid balance in the cochlea *is achieved in a two-fold way*: (1) by regulation of total blood flow into the cochlea through the sympathetic innervation of the labyrinthine artery and its major branches within the modiolus, and (2) by regulation of fluid balance between the intra- and extravascular fluids through the peripheral vascular bed. *Functionally* related to the latter control is the adrenergic innervation of the larger veins leaving the modiolus.

The peripheral regulatory effects of norepinephrine would appear to be of far greater significance to inner ear function than the adrenergic control of the labyrinthine artery *when the great numbers of fluorescing fibers* extending radialward in the osseous spiral lamina are compared with the small numbers of fluorescing fibers along the artery. Although electron microscopic studies indicate that some of the unmyelinated fibers in the nerve bundles of the osseous spiral lamina may lie within 750–1 000 Å of pericytes or perivascular sheaths of postcapillary venules, most of these fibers course among the myelinated fibers of the bundles. Thus, release of norepinephrine can occur some distance from the capillary bed into the surrounding tissue fluid. Acoustic nerve fibers, capillaries, and even the perikarya of the spiral ganglion may at time, or always, exist and function in a milieu rich in norepinephrine.

No close apposition (200 Å) of unmyelinated fibers with endothelial cells of capillaries, as reported by Terayama et al. (1968) to occur in the guinea pig, has been observed in the rat. This could be due to species variation.

The actual site or sites in the inner ear which are under the influence of norepinephrine can only be determined experimentally

Norepinephrine may affect the caliber or permeability of the local capillaries, although there is presently no evidence that norepinephrine has any effect upon blood vessels lacking smooth muscle in their walls On the other hand, norepinephrine released into the tissue fluid of the nerve bundles of the osseous spiral lamina could be carried into the capillaries and to the cells they nourish, to exert an influence upon their activity

It is proposed here that the adrenergic innervation of the cochlea is dual in function, affecting both auditory nerve activity at the site of the generator potential and the fluid balance. A third possibility that the fibers chemodynamically influence the sensory neurons, cannot be discounted at the present time. The existence of the adrenergic system in the inner ears of newborn kittens and puppies, when the sensory system is undergoing final development (Pujol & Marty 1970 also personal observations) and is presumably *nonfunctional* may indicate the existence of some trophic effect upon the growth of the acoustic neuronal dendrites or upon the organ of Corti itself On the other hand, the completeness of the adrenergic system in the newborn animals might be but a reflection of the critical importance of norepinephrine in maintaining the proper fluid medium in the inner ear at the time the organ of Corti is undergoing final development.

Summary

Fluorescence microscopic studies of the cochleae of the rat mouse kitten and puppy indicate that fluorescent adrenergic fibers are of dual distribution in the inner ear One group of fibers is perivascular to the major labyrinthine vessels and the other *more significant* group appears to course chiefly among cochlear nerve fibers and spiral ganglion cells. The latter group occurs in greatest numbers within the osseous spiral lamina where the fibers course in parallel array peripheralward. Some of the fluorescing fibers form arcades others project into the foramina nervosa where they end as terminal beads. Electron microscopic investigation of the rat cochlea supports the fluorescent results. Some unmyelinated fibers approach within 750–1 000 Å of membranes of pericytes associated with capillaries or post capillary venules in the root of or within the osseous spiral lamina but many course independently of the vessels. These results are interpreted as indicating a generalized function for norepinephrine in influencing fluid balance and in modifying auditory nerve activity at the periphery

Zusammenfassung

Fluoreszenzmikroskopische Studien der Schnecke bei Ratte Maus, Katzchen, und Hündchen zeigen dass die fluoreszierenden adrenergischen Fasern des Innenohrs in zwei Gruppen verteilt sind. Die eine Gruppe läuft perivaskulär an den grösseren Blutgefässen des Labyrinthes entlang, die andere bedeutendere Gruppe hat unter den Nervenfasern und zellen des Ganglion spirale ihren Verlauf Diese Gruppe kommt *hauptsächlich in der*

lamina spiralis ossea vor wo die Fasern in parallelen Bündeln gegen die Periferie verlaufen. Einzige fluoreszierende Fasern bilden Arkaden, während andere in den Foramina nervosa als *spheridae terminales* endigen. Elektronmikroskopische Untersuchungen der Schnecke der Ratte bestätigen die Fluoreszenz ergebnisse. Einzige myelinfreie Fasern laufen in nächster Nähe (750–1 000 A) der Grenzmembranen von Perioyten der Kapillargefässe oder postkapillare Venülen der Lamina ossea, viele aber sind ganz unabhängig von den Blutgefässen. Diese Ergebnisse werden als Zeugnis einer Allgemeinfunktion des Noradrenalins, das Flüssigkeitsgleichgewicht im Innenohr zu beeinflüssen und die Aktivität der Hörnerven zu modifizieren.

Acknowledgments

I am very grateful to Dr Joseph E. Hawkins, Jr for his encouragement and for his helpful comments during the preparation of this paper. I am also grateful to Dr Edward Lauer for his constructive criticism of the manuscript and to Dr William Burkel for the drawing used in Fig. 1. I thank Dr Rita Ping Liu for her technical assistance. All mice used in this study were obtained from the Mammalian Genetics Center at The University of Michigan through the courtesy of Dr Elizabeth Barto to whom I am deeply indebted.

INTRODUCTION

The spontaneous healing of a perforation in the drum membrane depends on the way it is caused and on the size of the defect. Small perforations which originate as a consequence of a trauma or result from an acute otitis media, usually heal rather rapidly. However large traumatic perforations tend to heal in the beginning, but the activity of the healing process gradually declines and often ceases *completely before the perforation* is closed. A perforation originating from a chronic otitis, may vary in size during the healing process, while no complete closure occurs. In these cases the main number of small perforations heals spontaneously after the disappearance of the inflammatory process, the larger ones however rarely.

The evolution in the techniques of closing a persisting perforation in the drum membrane can be divided into two periods. In the first period (1640–1952) starting with the first reported attempt of Banzer a great number of different methods were used to eliminate the harmful consequences of a persisting perforation in the drum membrane, initially with prostheses and afterwards with methods for the purpose of getting the perforation closed. The second period (1952 until now) is characterized by the entrance (Von Moritz, Wullstein and Zöllner) and further development of plastic surgical techniques to get functional reconstruction of the hearing organ. In this period successful healing of drum perforations was obtained with tissues of very different origin. However until now there has been *a large divergency in opinions as to the* usefulness of the tissues that had to be used in tympanic grafting. Moreover fundamental data on the healing process of a defect in the drum membrane and the effect of covering the defect with a graft are extremely scarce.

The present study was undertaken with the object of obtaining more insight in the wound-healing of the drum membrane. The first part of this monograph consists of a critical analysis of the methods of closing a persisting perforation in the drum membrane used until now. In the second part the results of an experimental study on the healing pattern of a traumatic perforation in the drum membrane with and without the use of a graft are described.

INTRODUCTION

The spontaneous healing of a perforation in the drum membrane depends on the way it is caused and on the size of the defect. Small perforations which originate as a consequence of a trauma or result from an acute otitis media, usually heal rather rapidly. However large traumatic perforations tend to heal in the beginning, but the activity of the healing process gradually declines and often ceases completely before the perforation is closed. A perforation originating from a chronic otitis, may vary in size during the healing process, while no complete closure occurs. In these cases the main number of small perforations heals spontaneously after the disappearance of the inflammatory process, the larger ones however rarely.

The evolution in the techniques of closing a persisting perforation in the drum membrane can be divided into two periods. In the first period (1640–1952) starting with the first reported attempt of Banzer, a great number of different methods were used to eliminate the harmful consequences of a persisting perforation in the drum membrane, initially with prostheses and afterwards with methods for the purpose of getting the perforation closed. The second period (1952 until now) is characterized by the entrance (Von Moritz, Wullstein and Zöllner) and further development of plastic surgical techniques to get functional reconstruction of the hearing organ. In this period successful healing of drum perforations was obtained with tissues of very different origin. However, until now there has been a large divergency in opinions as to the usefullness of the tissues that had to be used in tympanic grafting. Moreover fundamental data on the healing process of a defect in the drum membrane and the effect of covering the defect with a graft are extremely scarce.

The present study was undertaken with the object of obtaining more insight in the wound-healing of the drum membrane. The first part of this monograph consists of a critical analysis of the methods of closing a persisting perforation in the drum membrane used until now. In the second part the results of an experimental study on the healing pattern of a traumatic perforation in the drum membrane with and without the use of a graft are described.

CHAPTER I

ANALYSIS OF THE LITERATURE ON MYRINGOPLASTY

As already mentioned the historical development of the techniques used to eliminate the harmful effect of a persisting perforation in the drum membrane can be divided into two periods 1640–1952 and from 1952 until now Nearly all techniques used in the first period (reviewed by Schrimpf 1954 and Storrs, 1966) have been abandoned. Only the etching of the edges of the perforation with chemical caustics such as trichloracetic acid (Dunlap & Schuknecht, 1947) or silver nitrate are occasionally used at present to close small perforations. The effect of this procedure, which may be compared with the mechanical removal of the edges of a perforation performed as part of the surgical procedure in the period from 1952 until now is of fundamental importance to obtain healing of the perforation. When the inflammatory processes are healed the edges of a persisting perforation are avascular and consist only of strands of dense connective tissue covered with a thin layer of epithelium. Removal of this tissue (mechanically or with chemical caustics) will create a situation comparable with a fresh traumatic perforation. I this way the membrane is stimulated to proliferate. With the use of this method alone, the drum membrane will heal in a few cases only To obtain a higher score it is necessary to cover the perforation with a graft as may be concluded from the results obtained in the second period.

This period started with the introduction of the tympanoplastic surgery a surgical technique to obtain a functional reconstruction of the middle ear and the drum membrane (Von Moritz, 1952 Wullstein, 1952 Zöllner 1952). For the reconstruction of the drum membrane (myringoplasty) they used skin, as was previously used by Berthold (1878), Ely (1881) and Tangemann (1884) and afterwards by Shulbof and Valdez (1944).

The usefullness of skin for myringoplasty was already being discussed a few years after 1952 and afterwards many tissues have been used in tympanic grafting. From the variety of tissues used since that time (reviewed by Örtegren, 1964 and Salén, 1968) and still used it appears that there is no general view on the preferred tissue. This is most likely caused by the lack of sufficient experimental data on the behaviour and the fate of these tissues and their effect on the course of the healing process of the drum membrane. Moreover the arguments used by several authors in favour of a particular tissue are often obscure and founded insufficiently

In considering the present state of affairs it appears that skin, except meatal skin, is no longer used in myringoplasty The properties of the external body skin as drum membrane graft are such that sooner or later chance of failure is very high. Inflammation and excessive desquamation of the graft very often occur These phenomena are highly likely due to the change in the environmental conditions for the graft. The temperature and the humidity near the drum membrane (Nadel & Horvath, 1970) are much higher than at the retro-auricular region, from which the grafts usually originate. Since a full thickness skin graft is rather thick and does not grow much thinner even after several years (Guilford et al., 1965) less improvement in hearing will be obtained (Allen & Fernandez, 1960 Pesavento, 1960). Besides this, the chance of the development of a cholesteatoma in the

used in fact. Only homologous tissues stored at low temperatures, freeze dried or preserved with chemical agents have been used and these are consequently avital. Therefore there is no fundamental difference between these tissues and the membrane of Cargile used by Fox (1945). For that reason it is more correct to talk about implants. A striking phenomenon, however is that no real transplantation reactions were described. Since lyophylisation or preservation of tissues at 0 C (Cornish & Scott, 1966) do not destroy the antigenic properties, disappearance of these properties was only observed if tissues were preserved at temperatures below -20 C (Andresen et al., 1956). Although no data are available, it seems likely to assume that tissues preserved in sterilising fluids (merthiolate, cialit, merfen, ethanol) lose at least part of their antigenic capacity. Besides this, several reasons may be supplied to explain the absence of reactions suggestive of transplantation phenomena in using homologous tissue in myringoplasty.

1. The amount of transplanted tissue is so small that only a slight, subliminal quantity of antibodies is formed (dosage phenomenon of Medawar (1944).

2. The T-antigen, responsible for the transplantation reaction is confined to the nucleus. The homologous tissues used in myringoplasty are mainly composed of fibrous tissue containing only a few cells.

3. The amount of antibodies formed is dependent on the degree of vascularization of the acceptor site. In myringoplasty the initial contact between graft and drum membrane is very small. Moreover it may be supposed that the transplanted tissue might lose a large amount of its antigenic properties before complete integration into the membrane had been established. Therefore the concentration of antibodies may not reach the level to raise a graft rejection.

Support for these assumptions may be derived from the experiments of Cornish and Scott (1966). They implanted lyophylised homologous and heterologous cardiac valves in sheep. When these tissues were used in myringoplasty no graft rejection was observed, but transplanted into the musculus rectus abdominis, the reaction was vigorous. A comparable observation was done by van den Broek (1968) with incus grafts in rats. When a fresh homologous incus was transplanted into the middle ear no reaction was found. However when transplanted into the musculus tibialis anterior a transplantation reaction was observed.

Summarizing it may be concluded in view of these considerations that with a large number of the afore mentioned tissues a successful healing of persistent perforations in the drum membrane can be obtained. However it must be noted that there are some factors which make it very difficult to predict exactly the successful score which can be obtained with a definite graft.

1. There is a large variability in the surgical techniques used.

2. Many authors fail to report the size and the anatomical position of the perforation as well as the age of the patients. These factors may seriously influence the final results.

3. The follow-up periods are usually rather short. With many techniques the initial successful results appeared to decrease after longer follow-up periods. Therefore a follow-up period of at least several years seems necessary to make final conclusions on the used technique.

4. In many cases no data are reported on the cause of failure. In appreciating the usefulness of a tissue in myringoplasty it is very important to know if the failure is due to a recidive of the otitis or to the behaviour of the graft.

Apart from this and in spite of the lack of satisfactory data on the healing process of the drum membrane and the effect of the graft on this process, several important facts can be distilled from the reported clinical data to obtain successful healing of a persisting perforation in the drum membrane.

1. The middle ear space and the external meatus has to be free from inflammatory processes, when a functional reconstruction is being performed (Zöllner 1955). If this cannot be realized, the inflammatory process had to be

graft (Beickert, 1958) from transsected hair follicles and glands remains present until the graft is completely transformed into tissue of the drum membrane. This chance is much higher if split skin is used, since in this case a much higher number of these skin organs are transsected (Wullstein 1960) In addition to this, split skin may easily necrotize (House & Sheehy 1961 Guilford, 1962 Kraus et al 1964 Bellucci, 1966) and reperforation will occur In view of these considerations it will be clear that the long term results obtained with external body skin grafts were very bad 30–70 / failure (Beickert 1958 Thorburn 1960 1963 House & Sheehy 1961 Guilford, 1962 Mawson & Pickard, 1962 Wright 1963 Örtegren, 1964 Salén, 1964)

Far better results were obtained with pedicled (Frenckner 1955a, b Sooy 1964 Mulcahy & McAfee 1964 Robinson 1966) and free grafts (Plester & Nijsten, 1959 House & Sheehy 1961 Pfaltz et al 1962 Mulcahy & McAfee, 1964 Patterson et al 1967) from the deep part of the meatal skin The development of graft cholesteatoma is very unlikely because this part of the meatal skin does not contain hair follicles or glands Since this tissue is adapted to the temperature and the humidity of this region the absence of inflammatory processes and excessive desquamation can be explained Stenosis of the meatus sometimes occurring as a consequence of the healing of the denuded meatus (Sheehy 1964) is a disadvantage of this method Besides this, it must be noticed that the used meatal skin does not only consist of a layer of epithelium and subepithelial connective tissue, but also of a periosteal layer Therefore it seems likely to assume that the periosteal layer may contribute to the successful results, in view of the favourable results obtained with the use of periost only (Chiossone, 1964 Berger & Hessberg, 1965).

From the excellent results reported with autologous tissues of mesodermal origin like fascia (Heermann 1962 Örtegren 1964 Patterson et al. 1967 Sale 1969), vein (Austin & Shea 1961 Wright, 1963 Tabb & Rutledge, 1964 Austin, 1965) perichondrium (Goodhill et al., 1964) and fat from the ear lobe (Ringenberg, 1962) it seems reasonable to conclude that they are very suitable in myringoplasty The usefulness of some of them (ear-lobe fat, vein and perichondrium) is confined to small perforations, since the obtainable size of pieces of these tissues is not large enough to close large perforations. Moreover vein contains many elastic fibres, so the edges of the graft tend to curl and the contact with the drum is lost (Richards & McGee, 1965) Although initially successful results were obtained in about 90 / of the cases with meatal skin and autologous tissues of mesodermal origin a slight decrease of this percentage was observed after a follow-up period of several years. Wright (1963) and Austin (1965) suggested that in these cases the perforations were closed in highly atrophic membranes. They advised therefore the complete removal of this area. Moreover it appeared that these reperforations occurred in those ears in which a large perforation was present. This might have been an additional cause of the bad results To prevent reperforation in these cases, several surgeons decided to use combined grafts (Kley 1963 Kraus et al., 1964 Guilford, 1962 Mulcahy & McAfee, 1964 Bienias, 1964 Kup, 1967). The results appeared to be successful although reported follow-up periods are in many cases rather short and reperforation usually occurs one or two years post-operatively

During recent years homologous tissues (Schrimpf 1954 amnion Forman 1960 cornea Jansen, 1963 perichondrium Trombetta, 1963 pericard Nickel, 1963 Mitchell, 1967 Bogomilsky 1969 vein Chalat 1964 Marquet, 1968 drum membrane Albrite & Leigh 1966 dura) and even heterologous tissues (Cornish & Scott 1966 1968 cardiac valves Goodhill 1966 gelfoam) have been introduced in myringoplasty With some of those tissues the results seem as successful as with the autologous tissues of mesodermal origin However apart from the method of Chalat (1964), using vital homologous drum membranes, no real homografts have been

CHAPTER II

EXPERIMENTAL STUDY ON THE HEALING PROCESS OF THE DRUM MEMBRANE

A. INTRODUCTION

From the clinical data reported in the first chapter it will be clear that the use of tissue transplantation is essential for obtaining successful healing of a persisting perforation in the drum membrane. Some suggestions have been made on the role played by the graft in the healing process, but without adequate experimental evidence. Moreover fundamental data on the wound healing process of the drum membrane are extremely scarce.

In the past decennium, it is true, several animal studies on the integration of tissues in the drum membrane have been reported. But, except for the investigations of McMinn and Taylor (1966) who studied the early phase of the healing process they only concerned a small number of experiments in which the integration of different tissues was studied after follow-up periods of several months (Tiedemann, 1960 Withers et al., 1963 Richards & McGee, 1965 Paparella, 1967 Rogers & Snow 1968 Salén, 1968). The object of the present study was to examine the healing process of the drum membrane after producing a traumatic perforation and moreover to study the effect of transplanted tissues on this process and the fate of the grafts itself.

In the first part of this investigation, these problems were studied on cats with histological techniques. The second part deals with the same problems studied autoradiographically on the drum membrane of mice. With the latter technique more information could be obtained on the amount and the localization of the mitotic activity during the healing process.

B. HISTOLOGICAL STUDY IN CATS

1 Methods

The experiments were performed on adult cats weighing between two and four kg. The animals were anesthetised with sodium pentobarbital (30 mg/kg body weight) administered intraperitoneally. The surgical procedure was carried out using a Zeiss operating microscope, while surgical sterility was maintained. The drum membrane was reached from a retro-auricular incision after the meatus had been opened a few millimeters from the anulus tympanicus. With a needle a perforation (2–3 mm in diameter) was made in one of the ventral quadrants. In a certain number of ears the drum membrane was completely removed.

The perforations were left open or closed with autologous fat, connective tissue, full thickness skin from the meatus or with gelfoam (imbibed with wound fluid) and subsequently the retro-auricular wound was closed. Each animal received post-operatively 30.000 I U penicilline i.m. (Mycofarm) daily for three days. After survival times varying from one day to thirty weeks post-operatively the animals were sacrificed. The temporal bones were dissected and fixed in Bouin's solution after removal of the bony wall of the middle ear to facilitate fixation of the drum membrane. After 48 hours of fixation, the drum membrane and part of the meatal skin were dissected out after severing the connections between malleus and incus and tensor tympani. Then the specimens were decalcified in Kristensen's fluid, dehydrated in alcohol, embedded in paraffine and serially sectioned

eradicated in such a way that complete healing can be performed with antibiotics within a short time.

2 The tympanic membrane has to be stimulated to proliferate, either by mechanical or by chemical (etching) removal of the scar tissue from the edges of the perforation If the graft is placed on the outer side of the membrane the epithelium that may be covered by the graft has to be removed to avoid the development of cholesteatoma between graft and drum membrane.

3 The graft has to be fixed in such a way that no displacement can occur and the close contact with the drum will persist

4 The graft must show sufficient vitality or structural solidity (in the case of avital tissues or fresh tissues which may lose their vitality after transplantation) to close the perforation until the various layers of the drum membrane had closed the grap.

5 The graft may not develop pathological phenomena as a consequence of the change in environmental conditions, which may seriously interfere with the healing process.

6 The final resorption of the graft is not a necessary demand but important to obtain optimal hearing results.

(7μ) parallel to the long process of the malleus. The sections were stained with hematoxylin eosin

The next series of experiments were performed

1 Small perforations which were left open
2 Total perforations which were left open
3 Small perforations closed with fat.
4 Small perforations closed with connective tissue
5. Small perforations closed with full thickness skin
6 Small perforations closed with gelfoam.
7 Total perforations in which the middle ear and part of the meatus were filled with gel foam

From each series three ears of each survival time were studied

2 *The normal drum membrane*

Although the drum membrane of the cat is smaller and thinner than that in man there are no essential differences in structure. The middle layer of the pars tensa consists of two layers of collagenous bundles. Th fibres in the outer layer show a radial arrangement, those in the inner layer a circular The middle layer of the pars flaccida consists of more loose connective tissue, without special fibre arrangement On the outer side, the membrane is covered with keratinizing epithelium near the anulus and the handle of the malleus consisting of 2 to 3 celllayers and in the other parts of the membrane of one celllayer (Fig. 1) On its inner surface the membrane is lined by the mucous membrane of the tympanic cavity

3 *Small perforations which were left open*

The edge of a fresh perforation fixed within 30 min after perforating is shown in Fig. 2. In an area of about 100–300μ around the perforation the membrane was thickened, caused by swelling of the middle layer The epithelial and mucosal layers were usually retracted from the edge of the perforation.

After 24 hours the oedematous area was further extended. The middle layer was less stainable and often fragmented The epithelial cells showed a marked hypertrophy (Fig. 3) No remarkable changes were observed in the mucosa. During the next days the number of celllayers strongly increased, while keratinization occurred In some regions the epithelium migrated around the edge of the perforation and even below the membrane, making contact with the hypertrophic mucosa (Fig. 4). This situation however does not form the end of the healing process, as was suggested by Dunlap and Schuknecht (1947) These phenomena were most pronounced in the regions of the edge, situated close to the anulus, the handle of the malleus and the plicae mallei If the edge of the perfora

tion was on a greater distance from these sites, corresponding to a localization in the central part of the pars tensa, these phenomena were much less pronounced (Figs. 5, 6 7) These dif*ferences in activity remained present during the* entire healing process.

From the fourth day on, young mesenchymal cells could be found in the middle layer in the most active regions of the edge of the perforation Thereafter the number of these cells strongly increased, while also small capillaries became visible. In this stage of the healing process the difference in tissue activity in the various areas of the edges was most remarkable At the most active sites, the epithelium sometimes consisted of 15 to 20 celllayers while in these parts of the edge, situated in the centre of the pars tensa only 2 to 3 celllayers could be observed The same phenomenon applied to the amount of mesenchymal cells and the disappearance of the *fibres of the old middle layer (Figs. 5, 6 7) The* epithelium moved across the defect followed by the mesenchymal cells and the mucosa gradually narrowing the gap (Fig. 5). The defect was closed first by the confluence of the epithe*lium and afterwards by the middle layer and the* mucosa From this series of ears most perforations appeared to be closed after 10 to 14 days. In the next days the various tissues of the membrane gradually became thinner and about two weeks after closure, the drum membrane had regained its normal dimensions. Sometimes, epithelial cysts filled with horny lamels and persisting for longer periods, could be found in the healed part of the membrane (Fig. 8). The newly formed middle layer initially consisting *of connective tissue with many fibroblasts* was transformed within 4 to 8 weeks into a thin layer of dense connective tissue with only scattered fibroblasts. This new middle layer however failed to show the characteristic fibre *arrangement.*

From this series all traumatic perforations healed spontaneously except in one case in which the defect was not closed 23 weeks after perforating (Fig. 9) No inflammation or traces of a passed inflammatory process could be found in this case. The edges of the persisting perforation consisted of dense connective tissue, covered with a thin layer of epithelium A stri*king difference in the size of the edge was obser*ved dependent on the distance to anulus, handle of the malleus and plicae mallei The smallest part of the edge, situated in the central part of the pars tensa, consisted only of a small thickened border of dense connective tissue. The biggest part showed a large amount of irregular coursing strands of collagenous fibres in a large area At a short distance from this scar tissue the drum membrane showed its normal appearance (Fig. 10)

4 Total perforations which were left open

Although small perforations of the drum produced traumatically usually heal spontane*ously in animals as well as in man total or* subtotal defects only rarely heal in man Initially these defects tend to heal but complete closure occurs only incidentally For that reason we studied the healing process of the drum mem*brane in cats after complete removal of the mem*brane in ten ears, moreover part of the bony anulus and the adjacent meatal skin was removed in three ears.

No essential differences with the small perforations could be found in the healing process, except for a much more violent course of the process Seven days after removal of the drum a very thick rim of tissue was formed near the anulus. This rim consisted of a thick keratinizing epithelial layer covering the edge of the perfo*ration and a thick layer of highly vascularized* young connective tissue covered by the mucosa (Figs 11a b) The horny lamels were pushed forward in the direction of the regeneration The regenerative activity appeared to be largest in the upper parts of the anulus After two weeks a new membrane was formed on a distance of about 2 mm The epithelium consisting of about 10 to 15 celllayers at the edge of the perforation decreased to 2 to 3 celllayers towards

the anulus. A comparable decrease in thickness could be observed in the connective tissue Five weeks after removal of the membrane the defect appeared to be healed even in those ears in which part of the bony anulus had been removed The new membrane was nearly completely flat From the malleus, only the processus brevis and adjacent structures situated in the plane through the anulus were incorporated while the handle protruded free into the middle ear as was also recently reported by McIntire and Benitez (1970) The new membrane appeared to be composed of a thick middle layer consisting of connective tissue with many fibroblasts covered by two layers of epithelial cells and a one celllayer thick mucosa (Fig. 12) Locally accumulations of capricious coursing fibres were found (Fig. 13). In the next months the middle layer was transformed into a thin dense connective tissue layer with only scattered fibroblasts (Fig. 14)

In one ear a large epithelial cyst filled with keratine was observed on the handle of the malleus 20 weeks after perforating (Fig. 15) An open communication with the external meatus appeared to exist, as was concluded from the serial sections. Presumably this cyst originated from an incomplete removal of the epithelium from the malleus.

5 *Small perforations closed with fat*

In these ears small perforations were closed with subcutaneous fat, obtained from the retro-auricular wound

Twenty four hours after perforating the membrane showed an extensive oedema while a slight hyperplasia of the epithelium was observed near the edge of the perforation Generally the oedema was much more extensive in those ears in which the perforations were closed with a graft than in those which were left open The graft appeared to be more or less infiltrated by poly morphonuclear leucocytes, presumably already present in the tissue when it was dissected from the retro-auricular wound made 20 minutes earlier Leucocytes were also observed in the middle layer of the drum near the perforation. After 2 days the hyperplasia of the epithelium was strongly increased mainly in those regions where the edge of the perforation was situated close to the anulus, the plicae mallei and the processus longus The epithelial cells had been pushed up as it were against the graft resulting in a splitting into two layers one moving along the outer side of the graft and one along the medial side of the graft (Figs. 16a, b) After 4 days the migrating epithelium already covered a large part of the graft, while mesenchymal cells from the middle layer of the drum migrated into the graft. Simultaneously the mucosal layer started to migrate along the medial side of the graft. After one week the amount of mesenchymal cells in the graft was strongly increased, while also small capillaries were observed (Fig. 17) Immediately below the epithelial and mucosal layer a condensation of young fibroblasts was formed. Within two weeks the whole graft was covered with a thick epithelial layer on the outer side and a hypertrophic mucosal layer on its medial side. Underneath these epithelial linings a thick strand of vascularized connective tissue was formed. The short strands of epithelial cells, initially covering part of the medial side of the graft became surrounded by connective tissue at this stage and gradually disappeared within four to six weeks, while sometimes horny masses could be observed (Figs. 18 19) In the same time the epithelium and the mucosa gradually returned to their normal appearance. The fat grafts, revealing areas with lymphocytes and phagocytotic cells, appeared to be considerably decreased in size and were partly replaced by connective tissue. However a large individual difference in the condition of the grafts was observed. Sometimes nearly the whole graft was transformed into a flat disc of connective tissue, infiltrated by lymphocytes and foam cells (Fig. 20) In other cases a large quantity of fatty tissue surrounded by a layer of subepithelial and submucosal connective tissue was still present. These differences may—

at least partly due to the amount of fat which was transplanted In nearly all cases only small remnants of the graft could be found after five months. The remnants, consisting of fat cells, foam cells and some lymphocytes, were surrounded by a layer of dense connective tissue covered with an epithelial and mucosal layer which had its normal appearance (Fig. 21)

6 Small perforations closed with connective tissue

In these experiments subcutaneous connective tissue which was dissected from the retroauricular wound was used As in the fat grafts numerous polymorphonuclear leucocytes were observed in the transplanted connective tissue after twenty four hours. The course of the healing process showed a great resemblance to that in which fat was used The epithelium moved along the outer side of the graft and initially also at a short distance along the medial side, while occasionally epithelial cells in the graft were observed After about five days a massive migration of mesenchymal cells into the graft was found (Fig. 22)

Already a few days after transplantation the connective tissue revealed signs of degeneration This was concluded from the presence of pycnotic nuclei and a decrease in the stainability of the tissue After two weeks the main part of the graft appeared to be replaced by newly formed connective tissue containing numerous capillaries and lymphocytes. In this way as it were, a new cutaneous layer underneath the already closed hyperplastic layer was formed. At that time only poor stainable remnants of the connective tissue were present (Fig. 23) In the next weeks the epithelial layer became gradually thinner while close below the epithelium and mucosa a layer of dense connective tissue was formed, enclosing remnants of the graft and giant cells (Fig. 24) After five months the original position of the perforation could only be recognized by a slightly thickened middle layer containing rather many fibroblasts.

7 Small perforations closed with full thickness skin

The skin grafts were dissected from the canal wall about 3 mm outside the drum and placed over the perforation No retaining pack was used, because the graft adhered sufficiently to the drum membrane. The situation one week after transplantation is illustrated in Fig. 25. The meatal skin appeared to be composed of a very thick layer of dense connective tissue (dermis) containing some glands and hair follicles, covered with keratinized stratified squamous epithelium. After one week a thick epithelial layer moving up against the grafts, was observed at the transition of graft and drum membrane (Fig. 26). Sometimes this epithelium had already made contact with the epithelium of the skin. In the transitional zone mesenchymal cells and also small capillaries were already present in the graft The epithelium of the drum, at the edges of the perforation covered by the graft was hyperplastic.

After two weeks the epithelium of the drum was everywhere continuous with the graft epithelium In this stage the mucosal layer separated from the graft by a small layer of young connective tissue had already closed the gap. That part of the epithelium of the drum covered by the graft had lost its continuity and only small islands of swollen cells were found. The disappearance of this epithelium showed a striking resemblance with the one infiltrated in the fat and connective tissue grafts. After two weeks the amount of mesenchymal cells originating from the middle layer of the drum membrane was strongly increased in the graft replacing the original tissue of the dermis The residual part of the latter tissue was less stainable and contained pycnotic nuclei Moreover a large quantity of lymphocytes, especially close below the epithelium was observed

Four to six weeks after perforating, the hyperplasia of the epithelium was strongly decreased especially in the transitional zone. The main part of the original dermis had been replaced by new

Fig 26 Higher magnification of the transitional area between drum membrane and skin graft of Fig. 25 × 90.

connective tissue containing many fibroblasts while often a clear continuity between the middle layer of the membrane and the new dermis of the graft could be observed (Figs. 27 28, 29). Moreover a remarkable decrease in the number of hair follicles and glands was found. After two to three months no remnants of the original dermis were found. In this stage of the healing process part of the epithelium of the skin graft was quite similar to that of the drum membrane (Fig. 30). After six months the graft appeared to be strongly flattened by a decrease in size of the connective tissue layer

8. Small perforations closed with gelfoam

Besides the use of autologous tissues, we also studied the effect of gelfoam implants on the healing pattern of the drum membrane. In these experiments the traumatic perforations were closed with a small piece of sterile gelfoam imbibed with wound fluid.

After one day the same phenomena could be observed as with the use of autologous tissues. The gelfoam was infiltrated by a large amount of polymorphonuclear leucocytes, presumably arising from the wound fluid. A strong hyperplasia as well as a capricious infiltration of epithelium into the graft was observed after two days (Fig. 31), becoming much more extensive in the next days. This phenomenon was much more pronounced than in the cases of fat or connective tissue grafts, probably due to the spongy character of the gelfoam. After five days a great number of mesenchymal cells and capillaries were present in the middle layer of the membrane, but only a slight infiltration of these elements into the gelfoam was observed. After one week the epithelium, and also the mucosal layer had nearly closed the gap. The epithelial cells, both on the meatal surface and in the gelfoam, showed a pale and swollen appearance (Fig. 32). After two weeks a strong increase of the number of mesenchymal cells was found, while also small capillaries were present (Fig. 33). In this stage, the graft was covered with a thick keratinizing layer of epithelium, while islands of degenerating epithelial cells were present in the graft.

After four to five weeks no remnants of the gelfoam implant were observed. Immediately below the epithelial and mucosal layer a small strip of fibrous connective tissue was present. Between these layers a great number of lymphocytes, keratine and connective tissue strands were found (Fig. 34). In the following weeks the membrane became gradually thinner The epithelium and the mucosa showed their normal appearance after two months, while the middle layer was still rather thick, consisting of connective tissue with many fibroblasts (Fig. 35).

After five months this layer appeared to be transformed into dense connective tissue with only scattered fibroblasts. Occasionally local

thickenings, built up of collagenous fibres were observed.

9. *Total perforations closed with gelfoam*

In six ears the drum membrane had completely been removed and the middle ear cleft and part of the meatus had been filled up with gelfoam.

Within five weeks a new membrane appeared to have developed. In contrast with the total perforations which were left, the handle of the malleus was incorporated in the new membrane, although the membrane lacked the original conical shape. In most cases tissue bridges mainly composed of connective tissue lined with mucosa appeared to exist between the membrane and the medial wall of the middle ear (Fig. 36). In this stage of the healing process the epithelium consisted of several celllayers. The middle layer was very thick and appeared to consist of loose connective tissue except for the region immediately below the epithelium which contained a large amount of fibres (Fig. 36). In the following weeks the membrane gradually became thinner. The middle layer was transformed into a fibre rich connective tissue (Fig. 37).

After five months the thickness of the membrane was further decreased, although the middle layer revealing a large number of irregularities, was still rather rich in fibroblasts (Fig. 38). As in the other experiments, no signs of the characteristic fibre distribution in the normal membrane could be observed.

C AUTORADIOGRAPHICAL STUDY IN MICE

In the preceding study on the drum membrane of the cat a clear microscopic picture was obtained of the course of the healing process of a traumatic perforation and the effect of a tissue transplant on this process, in addition to its ultimate fate. However in view of the technique used no clear data could be obtained on the magnitude and the localization of the mitotic activity in the normal membrane and during the healing process. Therefore we decided to perform a series of identical experiments with the use of an autoradiographical technique as had been used by McMinn and Taylor (1966) and Litton (1968). In this way the mitotic activity could be determined at every wanted date, using radioactive thymidine (H -thymidine). This nucleoside is specifically incorporated into the chromosomal DNA in the S-phase of the mitotic cycle during which the amount of DNA is reduplicated (Quastler & Sherman, 1959). H thymidine disappears from the circulation within one hour after i.p. injection (Hughes et al., 1958) by destruction or excretion (von Potter et al., 1958). In this time all cells which are in the S-phase will incorporate this substance into their DNA. In our experiments we used a dose of 1µC/g body weight and an exposure-time of one hour. In view of this low dose and short exposition time, toxic effects and radiation damage to the cells may be excluded according to the experiments of Johnson and Cronkite (1959), Cronkite et al. (1961) and Fry and Lesher (1961). They all observed damaging effects only at much higher doses and longer exposition times.

This study was performed on the drum membrane of mice. Apart from the high amount of H -thymidine which would have been required if cats had been used, the drum membrane in mice can easily be surveyed and perforated without incising the meatus. In this way a possible influence of a wound in the meatus on the mitotic activity of the drum membrane could be excluded, although our experiments on cats did not give rise to such an influence.

1 *Methods*

The experiments were performed on Swiss mice (b.w. 18–25 g) anesthetized by means of an intraperitoneal injection of pernocton. With the use of a small glass funnel (diameter 1.5 mm) placed into the meatus, the drum membrane could be surveyed. Small perforations (0.5–1 mm diameter) were made with a glass needle. The perforations were left open or closed with a small

Fig 36. Section through the regenerated membrane partly connected with the medial wall of the middle ear 5 weeks after total perforation and filling up of the middle ear and part of the meatus with gelfoam. The middle layer of the membrane is very thick and consists of a subepithelial layer with many fibres and of a loose highly vascularised tissue towards the wall of the middle ear × 35.

piece of subcutaneous fat from the retro-auricular region. The surgical procedure was performed with sterilized instruments and with the use of an operation microscope.

After follow-up periods ranging from 18 hours to 3 weeks, 1μC H^3-thymidine (s.a. 1 9 C/mM Radiochemical Centre, Amersham, Engl.) per gram body weight was administered intraperitoneally. All animals were injected at 10.00 a.m. to avoid variations in the mitotic activity due to the diurnal rhythm and they were killed by decapitation one hour after injection of the isotope.

The whole petrous bone was dissected and after removal of part of the bony wall of the middle ear fixed for six hours in a solution containing 5 formaldehyde and 5 / trichloracetic acid, at 0 C. In this way the specimina were simultaneously fixed and decalcified without loss of nucleic acid content. After dehydration in graded alcohols the tissues were embedded in paraffine and sectioned serially (7μ). The sections were mounted on gelatinized slides and coated with Ilford G5 nuclear emulsion using the dipping technique (Kopriwa & Leblond, 1962). After an exposure time of 14 days the autoradiographs were developed, fixed, stained with methylgreen-pyronine and mounted in DPX. From each survival time four membranes were studied.

In order to obtain a survey of the localization of the labelled cells, the drum membrane was reconstructed with the use of the autoradiographs. For this reconstruction the sections 1 9 17 etc of the serially sectioned membrane were studied using the anulus and the handle of the malleus as fixed points. Each section was reproduced as a straight line, divided into segments, corresponding with 150μ of the membrane. The number of labelled cells was indicated at the base of each segment using different symbols for the epithelium, connective tissue and mucosa. In some cases the number of labelled cell could not be indicated in one diagram, because of the large amount of labelled cells in the various tissues. In these cases separate diagrams of the epithelium and connective tissue were made. Moreover from each drum membrane some characteristic sections were drawn, demonstrating the exact position of the labelled cells. The straight lines in the diagrams refer to the position of these sections. In addition the course of the thickness of the epithelial layer around the perforation during the healing process was visualized in a graph in order to compare this with the localization of the mitotic activity. For these graphs only sections coursing through the perforations have been used. The first section cuts the edges of the perforation near the handle of the malleus, the last one near the anulus. On the ordinate the thickness of the epithelial layer is indicated in μ above the zero line the thickness on the upper side of the perforation and below this line that underneath the perforation. The position of the lines, indicated by the arabic figures agrees with that in the diagram of the drum membrane.

The vascular pattern in the normal membrane and during the healing process was visualized by means of intracardial perfusion of the anesthetized animal with Indian ink. After completed injection the temporal bones were removed, fixed in formaldehyde and cleared in methyl benzoate after dehydration in alcohol.

2 *Morphology of the normal drum membrane*

A schematic drawing of the drum membrane of the mouse, including the fibre distribution (visualized with the polarization microscope) is shown in Fig. 39. Apart from the large surface of the pars flaccida, relative to the pars tensa, there are no important differences between the structure of the drum membrane of mice and that in men and cats. The long axis of the membrane measures about 3.5 mm and the short axis about 2.5 mm, while the minimal thickness of the pars tensa is only 3 4μ. The neck of the malleus is shell-shaped and its lateral edge incorporated in the membrane (Fig. 40) and perpendicular to the handle of the malleus has a fibrous connection with the bony anulus. The outer

2. *Morphology of the normal drum membrane*

A schematic drawing of the drum membrane of the mouse, including the fibre distribution (visualized with the polarization microscope) is shown in Fig. 39. Apart from the large surface of the pars flaccida, relative to the pars tensa, there are no important differences between the structure of the drum membrane of mice and that in men and cats. The long axis of the membrane measures about 3.5 mm and the short axis about 2.5 mm, while the minimal thickness of the pars tensa is only 3 4μ. The neck of the malleus is shell-shaped and its lateral edge incorporated in the membrane (Fig. 40) and perpendicular to the handle of the malleus has a fibrous connection with the bony anulus. The outer

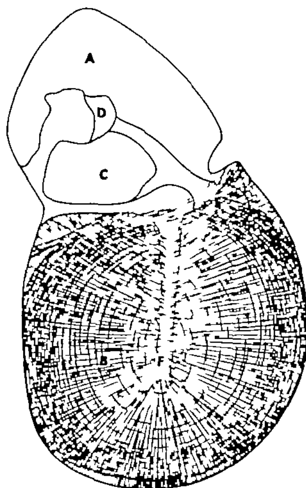

Fig 39 Schematic drawing of the drum membrane with fibre distribution of a mouse. A = pars flaccida, B = pars tensa, C = neck of the malleus, D = incudo-malleolar joint, E = processus brevis, F = handle of the malleus.

side of the membrane is covered with keratinizing squamous epithelium consisting of one celllayer except for the areas near the anulus and the handle of the malleus, where two celllayers can be observed (Fig. 41). Just as in other mammals the middle layer of the pars tensa is composed of an outer layer with a radial and an inner layer with a circular fibre arrangement, while the pars flaccida reveals no definite fibre distribution. At the inner side the membrane is covered with one layer of flat cells continuous with the epithelial lining (mucosa) of the middle ear In the vascular system three regions can be distinguished a marginal net near the anulus, a central net near the neck and the handle of the malleus and a vascular net in the pars flaccida (Fig. 42)

3 Mitotic activity in the normal drum membrane

The mitotic activity in the structures of the normal drum membrane in mice is shown in Fig. R1[1]). The localization of the labelled cells in the pars tensa appeared to be confined to a small area near the anulus and the handle of the malleus. In the pars flaccida however the labelling was scattered diffusely over the whole membrane. The ratio between the number of labelled epithelial cells, fibroblasts and mucosal cells was in the pars tensa 35 5 1 and 15 5 1 in the pars flaccida, the total number of labelled cells in both parts being about equal (n = 3) Since the surface area of the pars tensa is about twice that of the pars flaccida the mitotic activity in the structures of the pars flaccida is two times higher than in the pars tensa.

In Fig. R2 the mitotic activity in a drum membrane obtained from a mouse with a purulent middle ear disease is shown Compared to the normal membrane, the mitotic activity was extremely enhanced not only near the anulus, the handle of the malleus and the pars flaccida but even in the central part of the pars tensa. The same activity but to a lesser extent is applied to the connective tissue and the mucosa A micrograph of this ear (Fig. 43) shows the middle ear cleft filled with inflammatory cells. The outer surface of the membrane showed a thick keratinizing squamous epithelium while the dense connective tissue of the middle layer was transformed into a highly vascularized layer of connective tissue with a large amount of fibroblasts.

4 Small perforations which were left open

a. Pars tensa

About eighteen hours after perforating the pars tensa, the membrane, including the pars flaccida, was oedematous. Both epithelium and mucosa, which were slightly hypertrophic, were retracted from the edges of the perforation but to a larger degree than was observed in the drum membrane of the cat. In the membrane as well as in the middle ear cleft polymorphonuclear leucocytes were found

Fig. 42. The vascular pattern in the untreated drum membrane of mouse.

Fig 43 Section through the middle ear of a mouse with an inflammatory middle ear disease. The middle ear cavity contains many inflammatory cells. The epithelium of the drum membrane is stratified, while the thin layer of dense connective tissue of the middle layer is transformed into highly vascularised connective tissue with many fibroblasts × 90.

The number of labelled cells eighteen hours after perforating is shown in Fig. R3 The position of the retracted epithelium is indicated by the dotted line The retraction was less pronounced near the handle of the malleus than in the other areas Presumably this may originate from a firmer adherence of the epithelium to the middle layer in this region. Compared with the normal membrane no significant increase in the number of labelled cells was observed at that time.

After two days the amount of epithelial cells was strongly increased at the edge of the perforation especially in those areas where the edge was close to the malleus and the anulus (Fig. R4) as was also observed in the cat. Moreover the number of labelled epithelial cells was strongly enhanced near the anulus and the malleus and even in the pars flaccida (Fig R5) The same applied to the localization and the number of labelled mucosal and connective tissue cells, except for a remarkable high labelling of the mucosa on the handle of the malleus (Fig. R5 R6) The hyperplasia of the epithelium appeared to have been further increased after three days. Near the anulus, a slight hyperplasia of the mucosa was observed as well as the presence of mesenchymal cells. That part of the original middle layer denuded of epithelium and mucosa showed an avital appearance in this stage. A further increase in the amount of labelled cells was observed except for the pars flaccida (Fig. R7).

In the following days the hyperplasia of the epithelium further increased, while a clear migration towards the perforation was found, gradually narrowing the gap The hyperplasia was most remarkable in those parts of the edge situated close to the anulus and the handle of the malleus, as is illustrated in Fig. R8, while sometimes accumulations of dead epithelial cells were observed near the handle (Fig. R9) In this stage the mucosa was highly hyperplastic and was already moving towards the perforation. The diagrams in Fig. R9 and R10 not only show a further increase in the number of labelled cells, but also an enlargement of the area of mitotic activity towards the perforation

Only precisely at the outer edges where the epithelial cells were piled up no labelling was observed A further increase was also observed in the amount of labelled mesenchymal cells, mainly restricted to the anulus and the handle of the malleus The original avital lamina propria became gradually replaced by a layer of young connective tissue cells with some capillaries on the medial side covered with the hyperplastic mucosa The vascular pattern of the membrane, six days after perforation is shown in Fig 44. From a limited area of the vascular net in the anulus and the handle of the malleus new vessels appeared to have developed towards the healing perforation

After ten days most perforations were closed The mitotic activity decreased rapidly after

Fig. 44. The vascular pattern of the drum membrane, 6 days after producing a traumatic perforation (p) in the pars tensa.

closure of the epithelial layer. A few days later also the middle layer and the mucosa appeared to be closed. In the following days the epithelium became gradually thinner and two to three weeks after perforating the drum membrane had regained its original structure (Fig. R11). In the region where the perforation was made, only a few labelled cells were present. Except for a mucosal fold between drum and processus brevis and a small irregularity in the middle layer no essential differences with the normal membrane were found.

b. Pars flaccida

In view of the differences in structure and vascularization between pars tensa and pars flaccida, we studied the healing process of a traumatically produced perforation in the pars flaccida. Eighteen hours after perforating both epithelium and mucosa were retracted from the edge of the perforation, but to a much lower extent than in the pars tensa. The epithelium was hypertrophic and on the edge and in the middle ear cleft extravasated erythrocytes and also polymorphonuclear leucocytes were observed. The whole pars flaccida and the adjacent part of the meatal skin in which the pars flaccida gradually continues, showed a severe oedema. In some cases already a slight increase of the number of labelled cells was found in the pars flaccida, while a remarkable increase in labelling was observed in the anulus of the pars tensa, returning to its normal level after about three days (Fig. R12).

After three days the highly hyperplastic epithelium appeared to have migrated around the edge of the perforation. In this stage a large amount of labelled epithelial cells was present in the pars flaccida, in the adjacent part of the meatal skin and in the region of the handle of the malleus. In contrast to our findings after perforating the pars tensa, the localization of the labelled cells was not confined to distinct areas, but scattered diffusely on the whole surface. The mucosal lining of the pars flaccida, the ossicular chain and the wall of the middle ear as well as the submucosal connective tissue showed many labelled cells (Fig. R13).

In the following days the epithelium, followed by the connective tissue and the mucosal layer migrated towards the center of the perforation, closing the perforation in a concentrical way. The vascular pattern six days after perforating (Fig. 45) was quite different from that observed in the pars tensa. A characteristic pattern of vessels radiating towards the perforation had developed. Most perforations appeared to be healed after ten days and afterwards the pars flaccida regained its normal anatomical structure.

5 Small perforations closed with fat

On the analogy of our experiments on the cat, some fresh traumatically produced perforations in mice were closed with an autologous fat graft. Eighteen hours after transplantation no significant change in the mitotic activity was found. The retraction of the epithelium and mucosa was much less than if the perforations were left open. This may have been caused by the adherence of

the fat to these tissues. After two days the epithelium was already pushed up against the fat graft as was observed in the experiments on the cats (Figs. 46 47) The increase in the number of labelled cells appeared to be confined to the same areas as when the perforation was left open (Fig. R14) In the following days the epithelium migrated as a thick layer along the outer side of the graft, while the graft became infiltrated with mesenchymal cells from the middle layer of the membrane as was found in the cat Besides scattered capillaries and islands of fibroblasts in the graft, a clear concentration of these elements was found immediately below the epithelium nearly covering the whole transplanted tissue, and the mucosa (Fig. 48). In this stage a large amount of labelled cells was observed in the basal layer of the epithelium migrating along the graft, as well as in the graft itself (Fig. 49) After ten days nearly all perforations appeared to be closed The graft was covered by a thick layer of keratinizing epithelium. Between epithelium and the fat graft infiltrated by lymphocytes and fibroblasts, a thick layer of highly vascularized connective tissue was found (Fig. 50) On its medial surface the graft was covered by the mucosa. The mitotic activity had strongly decreased after closure of the perforation as is illustrated in Fig. R15. Afterwards the epithelium as well as the connective tissue layer became gradually thinner while the disappearance of the fat occurred just as we observed in the cat.

CHAPTER III

DISCUSSION AND CONCLUSIONS

From the results described it appears that a perforation produced traumatically in the drum membrane of the cat and mouse, just as in man usually heals spontaneously It seems likely to assume that a traumatically perforated normal drum membrane has a much better healing power than the membrane in which a perforation persists after healing of a past chronic otitis. This may be concluded from the fact that in the latter cases, the membrane rarely heals completely after removal of the tissue (scar tissue) at the edges of the perforation In this way a nearly comparable situation may be assumed to be created as in a drum membrane containing a fresh traumatically produced perforation. It has been proved that covering of the perforation with a piece of tissue, as discussed in chapter I is necessary to obtain complete healing. Later on in this discussion we will pay more attention to the function of the graft in the healing process

In our experiments only one case of a traumatically produced perforation in the drum membrane of a cat failed to heal after about six months (Figs. 9 and 10) This lack of healing is difficult to explain because no inflammation or traces of past inflammatory processes could be observed. The microscopical picture of the edges of the perforation, however agrees with that of a persisting perforation in the human membrane. The edge is avascular and consists of a large amount of scar tissue. From these pictures the necessary removal of this tissue, postulated in chapter I as a step in obtaining healing of the perforation will be clear

From the results obtained in the present experimental study the healing process of a traumatically perforated drum membrane may be characterized in the following way Although the drum membrane may be considered as part of the skin, the healing process is different. Bullough & Laurence (1959, 1960) have shown that wound healing of the external body skin occurs by the development of granulation tissue in the wound and an enhancement of the mitotic activity in the epithelium in a circular area around the wound. In the pars tensa of the drum membrane the healing process appeared to occur primarily by migration of epithelial cells from definite proliferative centers situated in or nearby the highly vascularized areas of the membrane, viz. the anulus, the handle of the malleus and the plicae mallei In this respect our experiments could not confirm the assumption of McMinn and Taylor (1966) that at first granulation tissue would be formed and secondly epithelial migration would take place

The migration of the epithelium appeared to occur in a nearly flat plane towards the center of the perforation Secondarily young mesenchymal cells became visible at a short distance from the outer edge of the migrating epithelium The magnitude of both epithelial and mesenchymal cell reaction in various parts of the edge of the perforation was highly dependant on the distance of the edge to the aforementioned vascular areas. (Figs. 5-7) This difference in activity in the various parts of the edge could also be observed in the perforation which did not heal completely It seems likely to assume that the epithelium in those parts of the edge which contain a large number of mesenchymal cells and also capillaries, will proliferate although this could not be confirmed definitely in the cat The formation of epithelial cells in the highly vascularized

areas will certainly contribute to a great extent in closing the perforation, considering the pictures we often observed in those parts of the edge situated in the centre of the pars tensa (Fig. 7). In these areas a large layer consisting only of epithelial cells appeared to migrate across the gap. In mice the main proliferative activity was initially confined to the anulus and the handle of the malleus after perforating the pars tensa. Afterwards this area simultaneously with the extension of the vascular system was enlarged towards the perforation (Figs. R3–R10, 44).

In this manner a traumatic perforation was first closed by the confluence of the epithelium and shortly afterwards followed by the layer of connective tissue cells and the mucosa. After closure, the enhanced mitotic activity decreased rapidly and the membrane gradually regained its original structure (Fig. R11), although no traces of the original fibre distribution (circular and radial) were observed.

The healing process of the drum membrane after a total perforation did not differ fundamentally from that of a small traumatic perforation, except for a much more violent reaction (Figs. 11a, b). This may be due to the traumatization of the highly vascularized areas of the drum. In this way the large gap can be closed. Since in all those ears a flat membrane was formed without the incorporation of the handle of the malleus, we came to the conclusion that the healing process was directed in a nearly flat plane through the anulus. Additional evidence for this conclusion might be derived from the micrograph in Fig. 11b, in which the horny lamels appeared to be pushed forward in this plane. From our experiments we could not conclude which mechanism underlies this directional growing pattern. However an inducing role of the anulus in the regeneration of the membrane as supposed by Goodhill (1966) seems unlikely since a new membrane was even formed if the main part of the bony anulus had been removed.

The large irregularities (Fig. 13) observed in these new membranes may presumably be ascribed to the more violent course of the healing process compared to the cases in which small perforations were made.

In contrast to the total perforations which were left, the handle of the malleus appeared to be incorporated into the new drum, however lacking the original conical shape, if the perforation was filled up with gelfoam. This may be caused by the infiltration of the gelfoam by fibroblasts and capillaries. In this way the handle of the malleus became surrounded by connective tissue which was continuous with the subepithelial connective tissue of the newly formed drum. The origin of the tissue bridges between the new membrane and the medial wall of the middle ear can be thought to develop in a similar way (Fig. 36).

The course of the healing process of a perforation which was closed with a graft appeared to be quite different from that of a perforation which was left open. After covering the defect with a graft, the migration of the epithelium in a flat plane was now blocked and the epithelial cells migrated mainly along the outer side of the graft (Figs. 16, 22, 25, 31 46, 47 R14). The small amount of epithelial cells which initially migrated along the medial side and into the graft disappeared after a short time. Afterwards the transplanted tissue was infiltrated by mesenchymal cells and capillaries and a condensation of these elements was formed immediately below the migrating epithelium and mucosa (Figs. 23, 48, 50). In this way part of the epithelium migrating along the graft had the opportunity to proliferate as could be definitevely proved in our experiments on the drum membrane of mice with the use of H^3-thymidine (Fig. 49). In this stage the bridging of the gap was not only dependent on the supply from distant proliferative areas.

After closure of the perforation reorganization occured. The new middle layer arose from the invaded fibroblasts, especially from the connective tissue which was formed below the epithelial and mucosal layer while the transplanted tissue was reabsorbed. No essential differences in the healing process were observed, if fat, connective tissue, full thickness skin or gelfoam were used, although there were differences in degree. The

CHAPTER III

DISCUSSION AND CONCLUSIONS

From the results described it appears that a perforation produced traumatically in the drum membrane of the cat and mouse, just as in man usually heals spontaneously It seems likely to assume that a traumatically perforated normal drum membrane has a much better healing power than the membrane in which a perforation persists after healing of a past chronic otitis. This may be concluded from the fact that in the latter cases, the membrane rarely heals completely after removal of the tissue (scar tissue) at the edges of the perforation In this way a nearly comparable situation may be assumed to be created as in a drum membrane containing a fresh traumatically produced perforation It has been proved that covering of the perforation with a piece of tissue, as discussed in chapter I is necessary to obtain complete healing. Later on in this discussion we will pay more attention to the function of the graft in the healing process.

In our experiments only one case of a traumatically produced perforation in the drum membrane of a cat failed to heal after about six months (Figs. 9 and 10). This lack of healing is difficult to explain because no inflammation or traces of past inflammatory processes could be observed The microscopical picture of the edges of the perforation however agrees with that of a persisting perforation in the human membrane. The edge is avascular and consists of a large amount of scar tissue. From these pictures the necessary removal of this tissue, postulated in chapter I as a step in obtaining healing of the perforation will be clear

From the results obtained in the present experimental study the healing process of a traumatically perforated drum membrane may be characterized in the following way Although the drum membrane may be considered as part of the skin the healing process is different Bullough & Laurence (1959, 1960) have shown that wound healing of the external body skin occurs by the development of granulation tissue in the wound and an enhancement of the mitotic activity in the epithelium in a circular area around the wound In the pars tensa of the drum membrane the healing process appeared to occur primarily by migration of epithelial cells from definite proliferative centers situated in or nearby the highly vascularized areas of the membrane, viz. the anulus, the handle of the malleus and the plicae mallei In this respect our experiments could not confirm the assumption of McMinn and Taylor (1966) that at first granulation tissue would be formed and secondly epithelial migration would take place

The migration of the epithelium appeared to occur in a nearly flat plane towards the center of the perforation. Secondarily young mesenchymal cells became visible at a short distance from the outer edge of the migrating epithelium. The magnitude of both epithelial and mesenchymal cell reaction in various parts of the edge of the perforation was highly dependant on the distance of the edge to the aforementioned vascular areas. (Figs. 5–7) This difference in activity in the various parts of the edge could also be observed in the perforation which did not heal completely It seems likely to assume that the epithelium in those parts of the edge which contain a large number of mesenchymal cells and also capillaries, will proliferate although this could not be confirmed definitely in the cat The formation of epithelial cells in the highly vascularized

migrate along the graft, which is simultaneously invaded by mesenchymal cells, while capillaries arise. In this way the migrating epithelium obtains a new well vascularized substratum, enabling the epithelium to proliferate (Fig. 49). Although our observations do not give rise to the existence of an effect of a humoral factor from the transplanted tissues on the healing process, this possibility cannot be completely rejected.

In view of these observations it seems likely to assume that a persisting perforation in a partly atrophic drum membrane with scar tissue as a consequence of a past chronic middle ear disease will not heal completely after removal of the scar tissue alone, since the membrane had lost part of its normal healing potency. In these cases successful closure can usually be obtained if the perforation is moreover covered with a graft. According to our observations, the transplanted tissue, becoming vascularized and infiltrated by mesenchymal cells, affords the epithelium which migrates along the graft, the opportunity to proliferate. By this the further course of the healing process is not only dependent on the proliferative activity which may be affected by the chronic disease, in the areas distant from the perforation. Moreover part of the tissue infiltrated into the graft contributes to the formation of the new middle layer. In this way the successful healing of persisting perforations, obtained with the use of various fresh and denatured grafts from different origin, satisfying the conditions presented in chapter I (p. 10), can at least partly be explained.

ACKNOWLEDGEMENTS

The authors wish to express their gratitude to Miss A. Jansen and Mr P. Spaan for their skilfull technical assistance, to Mrs M. Reijnen for typing and to Miss G. Kuijpers and Mrs J. Arick for correcting the manuscript.

speed of resorption is presumably highly dependent on the structure and the degree of loss of vitality during the first stage of the healing process, before revascularization of the graft has been established.

If gelfoam was used a more capricious and faster infiltration by epithelial cells was observed (Figs. 31 32) These phenomena as well as the rapid absorption are probably due to the spongy character of this substance

We will further go into the behaviour of meatal skin In contrast to the use of external body skin, no pathological phenomena were observed with deep meatal skin, as had been reported by Salén (1968) in a comparable experiment. This may be explained by the fact that the meatal skin is adapted to the climatological conditions in that part of the body We observed a gradual replacement of the dermal portion of the graft by connective tissue arising from the drum membrane (Figs. 28–30) while simultaneously a decrease in the number of hair follicles and gland structures was found In this respect our results disagree with the conclusions made by Salén (1968) after follow up periods of 14 and 25 weeks, that the meatal skin grafts usually integrate with retained viability size and character This difference may be at least partly due to the choice of the observation periods and the amount of transplanted tissue

On the fate of the original epithelium of the graft however we could not decide whether it was replaced by the epithelium of the drum or transformed into it. In view of the observations of McLoughlin (1961) showing a determination of the properties of epithelium by the subepithelial connective tissue, the epithelium of the graft may be transformed into the epithelium of the drum membrane, since the original dermal portion was replaced by connective tissue from the drum

Concerning the reaction of the two parts of the membrane (pars tensa and pars flaccida) a clear difference in the course of the healing process could be observed. In contrast to the healing process in the pars tensa, perforations made in the pars flaccida heal in a concentrical way (Figs. R13 45) This healing pattern showed a great resemblance to that of a defect in the skin, probably due to a greater similarity in structure and vascularization of skin and pars flaccida than of skin and pars tensa. The structure of the pars tensa is highly specialized to the function of sound perception The epithelium of the pars flaccida is because of its structure able to proliferate equally on its whole surface (Fig. 42). In the pars tensa we only observed this in pathological conditions (Fig. R2) The micrograph of the drum membrane of a mouse with an inflammatory middle ear disease (Fig. 43) revealed a transformation of the avascular lamina propria consisting of dense connective tissue into a highly vascularized loose connective tissue with many fibroblasts. In view of these observations, we are not able to conclude whether the cells in the central part of the pars tensa had lost their mitotic activity or whether they cannot divide because of the unfavourable nutritional conditions.

Summarizing the following conclusions may be drawn from this study The wound healing process of the pars tensa of the drum membrane is markedly different from that of external body skin while this process in the pars flaccida shows a great similarity with that of the skin.

The proliferative activity of the epithelium in the normal membrane and also in the first stage of the healing process is mainly confined to the areas with the largest vascular density viz. the anulus (also reported by Litton, 1968), the handle of the malleus, the plicae mallei and the pars flaccida The same applies to the origin of the fibroblasts and the mucosal cells, although the mucosal lining of the ossicular chain and the wall of the middle ear show a large mitotic activity during the healing process (Figs. R5 R10).

The healing of a traumatically produced perforation occurs first by the migration of epithelium from the aforementioned proliferative areas towards the perforation and afterwards also from certain regions nearby the perforation If a perforation is closed with a graft, the direction of the migration is changed and the epithelial cells

APPENDIX

Drum membranes reconstructed from autoradiographs

SUMMARY

The spontaneous healing of a perforation in the tympanic membrane depends on the way it is caused and on the size of the defect. Small perforations which appear as a consequence of a trauma or result from an acute otitis media usually close themselves rather rapidly However larger perforations and perforations arising as a consequence of a chronic middle ear inflammation only rarely heal spontaneously

At this moment a number of surgical techniques are available which can be used in most cases to close these defects of the tympanic membrane These procedures have in common that always a graft is used However a big gap exists in our knowledge of the fundamental aspects involved in the pattern of the wound healing of the tympanic membrane as well as of the role played in it by the graft.

The first part of this monograph contains a critical analysis of the methods used until now to close a persisting perforation of the drum membrane In this chapter it is attempted, on the basis of data from the literature, to select a number of conditions which apparently have to be fulfilled if reconstructive surgery of the tympanic membrane is likely to offer a reasonable chance of success.

In the second part (Chapter II) the results of an experimental study on the tympanic membrane in animals are presented These experiments were carried out on the tympanic membrane of the cat and the mouse In the cat common histological techniques were used in comparing the spontaneous healing process of the perforated tympanic membrane with the effect of using various types of grafts in closing the perforation.

Similar experiments were performed on mice with the use of an autoradiographical technique. Thanks to this latter technique the site and the extent of the mitotic activity of the healing process could be determined in the entire membrane at any given point of time.

From the results obtained it was concluded that the healing process of a perforation in the pars tensa strongly depends on the mitotic activity in fixed parts of the membrane the anulus, the plicae mallei and the handle of the malleus. Also under normal conditions the largest mitotic activity is located in these areas. The migration of the epithelial cells always runs approximately in a flat plane across the perforation The behaviour of the pars flaccida is different from that of the pars tensa both under normal and under traumatic circumstances.

When a perforation in the pars tensa is covered with a graft the migration pattern of the epithelial cells is disturbed. The epithelium is pushed up against the graft and can proliferate because the graft becomes vascularized.

In view of these findings the successful repair of a perforation in the drum membrane with a great number of fresh or denatured tissues may be explained

1 Introduction

Most of our knowledge about the hydromechanical action of the inner ear we owe to the admirable work of Georg von Békésy (1960 a). His direct observations of the basilar membrane vibration established the travelling wave pattern of disturbance as the mode of response by which the cochlea reacts to sound. Upon tonal stimulation of the inner ear a travelling wave appears on the cochlear partition whose wavelength becomes shorter as we proceed from base to apex. The envelope of the displacement wave has a flat basal and a steeper apical slope this gives the envelope its typical asymmetrical shape. The position of the rather flat envelope maximum depends on stimulus frequency it shifts with decreasing frequency progressively from the basal towards the apical end of the cochlea. Observing the excursion of points along the membrane as a function of frequency on Békésy obtained their frequency response curves. When expressed in db per octave the typical slope values of his response curves are 6 db per octave for the low frequency and 20 db per octave for the high frequency branch.

Von Békésy used in his studies stimulus frequencies of not more than 4 kHz, i.e. he worked in the apical, low frequency region of the basilar membrane. Recently the Mössbauer effect was put to use in studies of cochlear mechanics at the basal, high frequency end of the basilar membrane. Johnstone & Boyle (1967) and Johnstone (1969) working on the guinea pig obtained response curves with low frequency slope values of 12 db per octave and high frequency slope values of 70 to 100 db per octave at an SPL around 90 db. Rhode & Geisler (1969) measured in the squirrel monkey slope values of 5 to 10 db per octave on the low frequency side and 90 to 150 db per octave on the high frequency side.

It would seem that these more recent mechanical data conform better to the threshold-frequency response curves of primary auditory nerve fibres obtained by Tasaki (1954 1960) than do the curves of von Békésy However evidence compiled over the past few years on the discharge patterns of primary fibres makes it appear doubtful whether a simple relationship exists between the neural output from segments along the basilar membrane and the corresponding local mechanical input. Ingeniously devised experiments on the neural response to aperiodic stimuli (Kiang, 1965 de Boer 1969 Møller 1970) revealed a transducer mechanism with much less damping than is implied by the strongly damped response of the basilar membrane (Weiss, 1964 Flanagan, 1960 Siebert, 1962). Additionally threshold-frequency response curves (tuning curves) obtained by several investigators (Katsuki et al., 1958 Kiang, 1965 Evans, 1970 a) are relatively narrow over a considerable part of the dynamic range and fibres respond to a wide band of frequencies only at relatively high sound pressures. In view of this discrepancy between the neural output data and the mechanical input data of the cochlear transducer as far as frequency selectivity is concerned it seems necessary to postulate a sharpening mechanism intervening between the mechanical displacement of the membrane and the resulting neural discharges in auditory nerve fibres. However at present mechanical data are only available for stimulus intensities of 90 db SPL or above, i.e. from that part of the dynamic range where neural tuning curves are wide. Thus there is the important question whether

it is permissible to simply extrapolate mechanical data to sound pressures lower than 90 db SPL where the neural response is extremely sharply tuned

Since the study by Tasaki, Davis & Legouix (1952) it is well known that the excitation pattern along the basilar membrane may be investigated in an alternative way to that followed by von Békésy These authors inserted four pairs of differential electrodes into the four turns of the guinea pig s cochlea and they measured the longitudinal distribution of the cochlear microphonic (CM) in response to sinusoidal stimuli The resulting CM distributions and their dependence on stimulus frequency were qualitatively similar to von Békésy s observations on the vibratory pattern of the basilar membrane Legouix (1965/6 1969), using the same technique studied the CM in response to impulsive stimuli His findings are in good qualitative agreement with mechanical data the transient CM response shows the typical strongly damped oscillations with a natural frequency characteristic to the region of the basilar membrane from which an electrode is recording There is good evidence that the CM response is associated with the shearing motion at the hair bearing end of the sensory hair cells (von Békésy 1960 a) and that it originates in the region of the receptor pole of the hair cells (Tasaki et al 1954) That is why we shall use throughout this study the term hair-cell generator when strictly speaking, we only mean the source of the CM in the organ of Corti

Thus there are basically two ways in which the excitation pattern along the basilar membrane may be studied In the one mechanical excursions are measured directly In the other measurement is made of the electrical potentials which are the consequence of the mechanical excursions The greater sensitivity inherent in the electrical method offers the advantage that the CM can be used to explore the excitation pattern in the region of lower sound pressures, i e in the region below 90 db where the minute membrane deflections have not yet been resolved by mechanical methods. The disadvantage of the electrical method, however is one of data interpretation In the past there has been considerable uncertainty on the question how to evaluate exactly CM recordings taken with electrodes from the cochlear fluids. This question concerns the relationship between the potentials generated within the organ of Corti and those picked up by recording electrodes. A constructive step towards a better understanding was taken by Whitfield & Ross (1965) in a theoretical study They defined mathematically the relationship between hair-cell generator potentials and electrode outputs. According to this definition an electrode records the 'weighted sum of the electrical activity along the membrane. This, it is argued is due to the fact that hair-cell potentials spread out and interfere with each other to a considerable extent in the inner ear fluids. Thus the spatial spread of signals in the cochlea was recognised to be instrumental to the quantitative interpretation of CM data and a reappraisal of CM measurements seemed appropriate

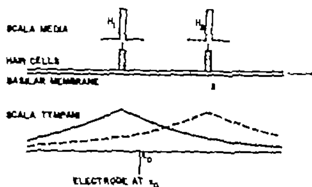

Fig 1.1 Diagram to show the interference of hair-cell outputs (H_1 and H_2) in the cochlear fluids due to signal spread along the canals. Electrode at x_0 records a potential which is the sum of the attenuated contributions from hair-cell generators at x_1 and x_2.

The present investigation developed logically from the mathematical formula relating hair cell output to electrode output In Fig. 1 1 two hair-cell generators are schematically shown, situated on the basilar membrane at points x_1 and x_2 respectively Let H_1 be the electrical

output at x_1 and H_2 that at x_2. H and H_2 are represented as spatial impulses. Each hair-cell generator establishes a potential field according to the conductive properties of inner ear tissues and fluids. The decay of potential strength with longitudinal distance from the generating source is indicated for scala tympani by an exponential attenuation function. It can be clearly seen from the illustration that an electrode at point x_e records a potential which is the sum, or superposition of the contributions from the generators at x and x_2. In the case of n hair-cell generators we obtain as expression for the electrical output at x_e

$$CM(x_e) = \sum_i H_i(x_i) w(x - x_i)$$

$w(x_e - x_i)$ is a weighting factor which takes account of the signal attenuation between the point of generation x_i and the recording site x_e. We may conceive of the basilar membrane as infinitely densely packed with hair-cell operators and consequently arrive at an integral expression for the CM at x_e.

$$CM(x_e) = \int_{-\infty}^{\infty} H(x)\, W(x_e - x)\, dx \qquad (1)$$

Equation (1) is fundamental to the present study. It defines the relationship between the hair-cell output pattern along the basilar membrane, $H(x)$, and the resulting CM distribution along the cochlear scalae, $CM(x_e)$. $W(x_e - x)$ is a weighting function which brings into play the signal attenuation effective between the points x and x_e. The expression in equation (1) is a convolution integral and by analogy to linear communication theory we may call the connection between $H(x)$ and $CM(x_e)$ a 'spatial filter operation'. Hence $H(x)$ is the input function and $CM(x_e)$ the corresponding output function. $W(x)$ is the spatial impulse response of the system.

Experiments to be described here were designed to examine the validity of equation (1). A suitable starting point seemed to be the study of CM distributions in response to high frequency tones. Such stimuli cause disturbances only in the basal coil of the cochlea and it seemed possible to measure very accurately and completely the corresponding CM patterns with a multi-electrode array arranged along the basal cochlea. At high frequencies the travelling waves have very short wavelengths and thus closely neighbouring hair cells are driven out of phase. One might expect therefore that phase cancellation is much more pronounced and that the spatial filter effect can be seen much better at high frequencies than at low ones.

it is permissible to simply extrapolate mechanical data to sound pressures lower than 90 db SPL where the neural response is extremely sharply tuned.

Since the study by Tasaki, Davis & Legouix (1952) it is well known that the excitation pattern along the basilar membrane may be investigated in an alternative way to that followed by von Békésy. These authors inserted *four pairs of differential* electrodes *into the* four turns of the guinea pig's cochlea and they measured the longitudinal distribution of the cochlear microphonic (CM) in response to sinusoidal stimuli. The resulting CM distributions and their dependence on stimulus frequency were qualitatively similar to von Békésy's observations on the vibratory pattern of the basilar membrane. Legouix (1965/6, 1969) using the same technique, *studied the CM in* response to impulsive stimuli. His findings are in good qualitative agreement with mechanical data: the transient CM response shows the typical, strongly damped oscillations with a natural frequency characteristic to the region of the basilar membrane from which an electrode is recording. *There is* good evidence that the CM response is associated with the *shearing motion* at the hair bearing end of the sensory hair cells (von Békésy, 1960 *a*) and that it originates in the region of the receptor pole of the hair cells (Tasaki et al., 1954). That is why we shall use throughout this study the term "hair-cell generator" when, strictly speaking, we only mean "the source of the CM *in the organ of Corti*".

Thus there are basically two ways in which the excitation pattern along the basilar membrane may be studied. In the one mechanical excursions are measured directly. In the other measurement is made of the electrical potentials which are the consequence of the mechanical excursions. The greater sensitivity inherent in the electrical method offers the advantage that the CM can be used to explore the excitation pattern in the region of lower sound pressures, i.e. in the region below 90 db where the minute membrane deflections have

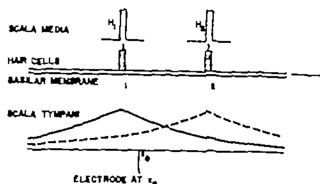

Fig. 1.1. Diagram to show the interference of hair-cell outputs (H_1 and H_2) in the cochlear fluids due to signal spread along the canals. Electrode at x_0 records a potential which is the sum of the attenuated contributions from hair-cell generators at x_1 and x_2.

not yet been resolved by mechanical methods. The disadvantage of the electrical method *however is one of data interpretation*. In the past there has been considerable uncertainty on the question how to evaluate exactly CM recordings taken with electrodes from the cochlear fluids. This question concerns the relationship between the potentials generated within the organ of Corti and those picked up by recording electrodes. A constructive step towards a better understanding was taken by Whitfield & Ross (1965) in a theoretical study. They defined mathematically the relationship between hair-cell generator potentials and electrode outputs. According to this definition an electrode records the "weighted sum" of the electrical activity along the membrane. This, it is argued, is due to the fact that hair-cell *potentials spread out and interfere* with each other to a considerable extent in the inner ear fluids. Thus the spatial spread of signals in the cochlea was recognised to be instrumental to the quantitative interpretation of CM data and a reappraisal of CM measurements seemed appropriate.

The present investigation developed logically from the mathematical formula relating hair cell output to electrode output. In Fig. 1.1 two hair-cell generators are schematically shown situated on the basilar membrane at points x_1 and x_2 respectively. Let H_1 be the electrical

our case, outweigh the advantage of recording potentials larger by 6 db

The problem of arranging a set of recording electrodes over a short length of the basilar membrane seemed to be most elegantly tackled by the use of a multi-electrode probe manufactured with the modern techniques of micro-miniaturization. Such a probe was manufactured for this project in the Lucas Research Department, Shirley Birmingham. Twelve narrow stripes of aluminium were photoetched onto a glass substrate which was cut into a rectangular shape appropriate for the insertion of the probe through a slit into scala tympani. However this approach proved unsuccessful because the probe was brittle and much too delicate to be repeatedly used in a large series of experiments. Thus very early on, during the exploratory phase of the project, the probe broke and this technique was discontinued. After this failure an alternative technique was adopted. A series of up to twelve holes was drilled into the wall of the basal scala tympani parallel to the basilar membrane and stainless steel wire electrodes were inserted into the holes. The placement of electrodes was extremely time-consuming. This method was finally abandoned in favour of the ultimate, optimum technique which allowed the rapid collection of data. A multi-electrode array was constructed by gluing insulated stainless steel wires together The elastic, ribbon-like array thus formed could be easily inserted through a slit into scala tympani alongside the basilar membrane

SURGICAL PROCEDURE

All guinea pigs were anaesthetised with Urethane administered intraperitoneally at a dose of 1.25 g kg. Tracheotomy was performed and a short polythene cannula was inserted into the trachea. The bulla on the animal's right side was exposed in the standard latero-ventral fashion described by Tasaki & Fernández (1952). Then the animal was mounted in a stereotaxic instrument with the head rigidly clamped between the skull and the upper jaw bone in a head holder The external auditory meatus was exposed and cut across leaving only a short sleeve for the insertion of the coupling tube of the earphone.

With a number of wire hooks the tissue surrounding the bulla was carefully retracted. The bulla was opened with a dental drill and part of the bony shell was removed with a forceps. Thereafter the cochlea protruding into the middle ear cavity was conveniently accessible for surgical manipulation. With small pieces of cotton wool the surface of the cochlea was cleaned and dried.

After these preliminary operations microdissection began with the aid of a Zeiss otoscope which both illuminated and magnified the operative field. With a small, round dental burr (1/4 C. Ash & Sons) the wall of the basal 1/2 turn of scala tympani was thinned down to uniform thickness along the course of the basilar membrane. The thickness was reduced until the bony wall was almost transparent. This procedure had to be executed with utmost care. Accidental sideways slipping of the burr by only about 1 mm and subsequent injury to the retracted tissue in the immediate vicinity could cause bleeding and filling of the middle ear cavity with blood. Removal of blood clots especially from the stapedial region was very delicate. It was found empirically that guinea pigs weighing about 500 g possessed cochlear walls with the optimum mechanical consistency for this operation. Guinea pigs below this weight had cochleae too fragile and heavier animals usually had a bony shell too hard and brittle. In either extreme case it could easily happen that the cochlear shell broke during the drilling process.

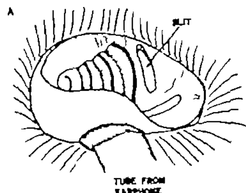
In the early experiments (single electrode technique) a number of holes were drilled with a stiff needle into the wall of scala tympani parallel to the basilar membrane. Since it was desirable to accomplish a fairly regular spacing of the holes the needle was mounted in a heavy handle. The weight of the handle stabilized the needle once it was placed on the

2 Methods

For the study of the spatial filter effect it was necessary to obtain a detailed picture of the CM distribution over a sufficient length of the cochlea. Analysis of the microstructure of CM patterns with equation (1) seemed only a *promising enterprise provided accurate* and reliable data about the longitudinal course of the CM were made available. The accommodation of an assembly of closely spaced electrodes allowing the detailed inspection of CM patterns was the central problem in the development of suitable techniques.

The set of recording electrodes was placed *in the basal scala tympani of the guinea pig's* cochlea. This site was chosen for mainly two reasons. First this part of the cochlea appeared to be spacious enough to allow the insertion of several electrodes without damage to the cochlear partition. Second the CM response to high frequency stimuli was expected to show the spatial filter effect most clearly. It was therefore imperative to execute measurements in the basal area where the response to such stimuli is known to occur.

The choice of the basal cochlea as recording site carried the advantage that the conditions of current spread have been studied most extensively for this part of the cochlear ducts (see Section 3 Weighting Function). As to the question which recording technique *should* be used, the differential technique with a set of paired electrodes along the cochlear partition or the simpler technique with a set of electrodes in one scala and a common reference electrode outside the cochlea, e.g. on the animal neck, there seemed to be no objection from existing evidence to using the simpler *technique. For CM recordings from* the upper turns of the guinea pig's cochlea most workers have preferred the differential technique, i.e. they recorded the potential difference between one electrode in scala tympani and one opposite in scala vestibuli. It has been suggested in the literature (Tasaki et al. 1952, Tasaki & Fernández, 1952) that the differential technique is superior to the alternative of measuring potentials between one electrode in scala tympani and the other on the neck. A differential pair of electrodes is supposed to record potentials only from one turn without contamination by signals arising from neighbouring turns. However Tasaki & Fernández felt that for the basal coil such a superiority did not exist and they stated: The microphonic recorded with one electrode on the neck and the other in the basal turn, either in scala vestibuli or in scala tympani, gives information as to the activity taking place in the basal turn without contamination by the responses originating in the upper turns. Recently Dallos (1969 *a*) confirmed this statement in a thorough study. Apart from the fact that the differential technique recorded potentials larger by 6 db in the basal turn he could not find any advantage over the simpler technique, i.e. one electrode in the basal scala tympani and the reference on the neck. In our case the simpler technique is preferable for mainly two reasons. 1) The *technical difficulties in setting up a differential* recording situation with twelve closely spaced pairs of electrodes are most probably prohibitive. 2) Cross-conduction between scala vestibuli and scala tympani via the fluid leaking out of the openings in the cochlear wall would probably be unavoidable. This would introduce uncontrollable current loops short-circuiting the cochlear partition. Thus it is clear that the disadvantages of the differential technique in



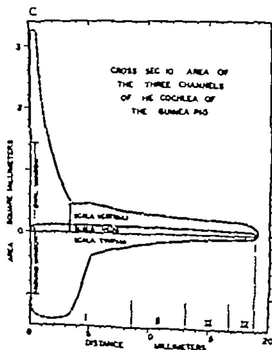


Fig. 2.1 (A) Schematic drawing of the exposed right cochlea of the guinea pig. The slit in the wall of the basal 1/2 turn of scala tympani is shown. (It is in the experiments approximately 2 mm long and 0.5 mm wide.) The slit runs parallel to the basilar membrane. The position of the stria vascularis is marked as a dark band.

(B) Right cochlea of the guinea pig with organ of Corti exposed. This photograph was taken from Engström et al. (1964). The schematic representation of the electrode array tips was superimposed on the photograph in order to show the approximate array position relative to the basilar membrane.

(C) Cross section area of canals according to Fernández (1952). The slit in the wall of scala tympani would—when plotted in this graph—extend from about 3 to 5 mm along the abscissa. The most basal electrode of the array 1 would be located between 3 to 3.5 mm.

completely and there was no danger of further formation of blood clots. Finally the Ringer fluid was sucked out of the middle ear cavity without, however removing fluid from scala tympani.

Then with a micromanipulator arrangement the multi-electrode array was inserted through the slit into scala tympani to a depth of about 300 to 400 μ. The tips of the recording electrodes were thus located in a line running at a distance of about 500 μ parallel to the basilar membrane.

THE MULTI-ELECTRODE PROBE

A. Manufacture of the array

The multi-electrode probe was the central piece of equipment for the measurement of

bony wall and prevented sideways slipping Up to twelve separate holes could be drilled in this way each with a diameter of about 70–100 μ Insulated 50 μ stainless steel wire electrodes were inserted into the holes. The insulation coating formed small blobs along the shaft of the electrodes and 400 μ away from a suitably shaped blob the electrodes were cut before insertion. Thus each individual electrode was selected and matched to a particular hole, the blob serving as depth control and as closure of the hole The steel wires had just the right combination of flexibility and stiffness which was essential for the successful placement of a set of electrodes. Thus previous attempts with more flexible silver electrodes failed The steel electrodes were about 50 mm long and were soldered to slim cylindrically shaped handles made of brass. After an electrode was inserted into scala tympani the brass handle was pushed into a complementary brass cylinder arranged in a perspex block (see Fig 2 6). The elastic force due to the bending of the electrode between the points of fixation—i.e. the hole in scala tympani and the perspex block—pressed the electrode slightly against the hole and thus held the electrode in a stable position This stabilization was extremely important since during the course of inserting electrodes it was impossible not to touch and disturb electrodes already in place it is only by virtue of the springiness of the steel wires that electrodes stayed in place despite disturbances The minimum distance between the holes could not be reduced below 0 3 mm without breaking the bony ridges between holes. With the need for more closely spaced electrodes the single electrode technique was abandoned in favour of the multi-electrode technique

In the latter technique a multi-electrode array was inserted into a slit like opening in the wall of scala tympani. The slit was manufactured in one of two ways. Drilling of a series of adjacent holes by means of a steel needle and subsequent breaking of the bony bridges between holes with a fine forceps was the one way As alternative to this indirect method there was the direct way of drilling the slit with a small, round dental burr (1/4 C. Ash & Sons). Extreme care and an absolutely steady hand were prerequisite for the success of this procedure. It was necessary to widen the slit so formed in both cases with a fine forceps. The shape of the slit was made to match the dimensions of the electrode array by cautiously breaking minute pieces of bone from the rims of the slit Care had to be taken not to approach too closely the region of the attachment of the basilar membrane to the wall of scala tympani The slit had a length of about 2 mm and a width of about 0.5 mm. It extended from about 3 to 5 mm along the basilar membrane measuring from the basal end of the membrane (see Fig. 2.1 A, B C).

Small blood vessels lining the floor of scala tympani opposite to the basilar membrane were usually injured during the formation of the slit. As a consequence blood clots formed inside scala tympani and it was clear that these clots would seriously distort the pattern of electrical conductivity in the scala. Attempts to remove the blood clots with a fine forceps were usually fatal because the sharp prongs of the forceps easily pierced the thin bony floor of scala tympani towards the modiolar core. In these cases the CM recorded from the basal scala tympani had a very low amplitude and there was practically no longitudinal phase variation Obviously the accidental hole in the modiolar wall effectively earthed scala tympani via the VIII nerve (see von Békésy 1960 a p 660). In order to remove the blood clots from the duct another procedure was adopted. The middle ear cavity was filled with mammalian Ringer solution so that the slit in scala tympani was well below the fluid level. A syringe also filled with Ringer solution, was held over the slit and the plunger of the syringe was slowly moved inwards and outwards. This produced streaming of fluid and effectively washed out the blood clots from scala tympani This procedure was repeated several times until it was certain that bleeding had ceased

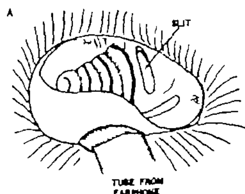

Fig. 2.I (A) Schematic drawing of the exposed right cochlea of the guinea pig. The slit in the wall of the basal 1/2 turn of scala tympani is shown. (C) Cross section area of canals according to Fernández (1952). The slit in the wall of scala tympani *would—when plotted in this graph—extend from* about 3 to 5 mm along the abscissa. The most basal electrode of the array 1 would be located between 3 to 3.5 mm.

completely and there was no danger of further formation of blood clots. Finally the Ringer fluid was sucked out of the middle ear cavity without, however removing fluid from scala tympani.

Then with a micromanipulator arrangement the multi-electrode array was inserted through the slit into scala tympani to a depth of about 300 to 400 μ. The tips of the recording electrodes were thus located in a line running at a distance of about 500 μ parallel to the basilar membrane.

THE MULTI ELECTRODE PROBE

A. Manufacture of the array

The multi-electrode probe was the central piece of equipment for the measurement of

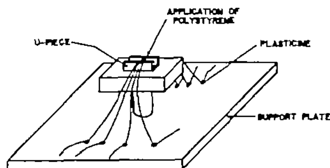

Fig 2.2 Schematic drawing of the wire assembly arrangement.

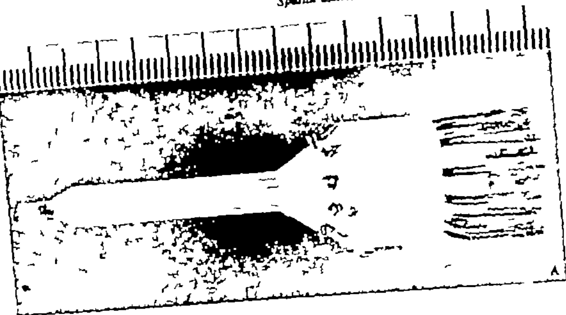
the longitudinal distribution of the CM response The individual electrodes composing the probe were made of the same 50 μ stainless steel wire which was used in the single electrode technique. Steel wires, about 150 mm long were slowly drawn through a bath of Bakelite Insulating Lacquer The coat so formed was then baked for not less than 20 min in an oven at 180 C. Wires were given at least three coats.



Twelve insulated wires were assembled side by side in a single plane and they were bonded together with polystyrene. The assemblage was carried out under visual control (Zeiss otoscope) In order to achieve an accurate alignment of the electrodes in a single plane the wires were pulled over the edges of a U shaped piece of metal. A schematic drawing of the simple assembly arrangement is given in Fig 2.2. The procedure began by tightly pulling the first insulated wire over the U piece and fixing the wire ends on the 'support plate with plasticine The second wire was arranged in the same way close to the first one With a paint brush a small droplet of a polystyrene benzene solution was spread along the electrode wires over a length of about 15 mm Due to the surface tension of the liquid the wires were pulled close together The polystyrene dried rapidly and fixed the wires. Then the third electrode was bonded to the second one and the manipulation was repeated until all twelve electrode wires were glued together In the event that any particular wire within the set was not aligned properly a small drop of benzene was applied so that the polystyrene softened locally This made a realignment of the wire possible.

The distance between adjacent electrode wires was mainly determined by the blob-like thickenings of the insulation coating along the wires. It was possible to achieve a regular spacing of electrode wires in the array by carefully selecting wires with approximately equal blob sizes. Thus the distance between the centres of adjacent electrodes varied from about 150 to 180 μ Since the electrode diameter was 50 μ this variation in distance was considered tolerable.

B. Mounting of the electrode array

One end of the assembly of wires was trimmed with scissors and the completed ribbon like array was then mounted on the electrode probe carrier' (see Fig. 2.3 A) A rectangular piece of ordinary film tape was glued to the small metal lip sticking out of the carrier shaft. The electrode array was bonded with Eastman adhesive 910 to this flexible tape support in such a way that about 8 mm of the ribbon like array protruded beyond the support. A schematic drawing of this arrangement is given in Fig. 2.3 B The free ends of the electrode wires were embedded with polystyrene in twelve grooves cut lengthwise into the round shaft of the carrier Finally after scraping off the insulation from the terminal section with a scalpel the electrode wires were soldered to twelve small steel bars permanently attached to the upper end of the carrier The carrier was made of heat resisting Teflon to avoid melting of carrier material during soldering

The carrier was then connected to the main part of the array holding unit (see Fig 2.4). This part consisted of a round perspex shaft with twelve permanently embedded steel wires leading to twelve preamplifiers arranged at the top end of the shaft. A short, cylindrical piece of perspex was inserted between the probe

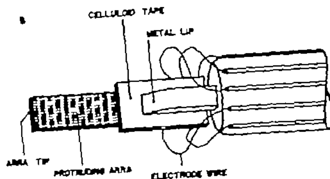


Fig. 2.3 (A) Photograph of the 'electrode probe carrier' (scale division in mm).

(B) Schematic drawing of the tip of the 'electrode probe carrier' with the electrode array mounted.

carrier and the main shaft. It contained the electrical components necessary for the a.c. coupling between electrodes and preamplifiers. (For the measurement of cochlear d.c.-potentials this a.c.-coupler could be removed. In the experiments reported here no d.c.-measurements were undertaken and the a.c.-coupler was always in place.)

The shape of the complete electrode array holding unit represented a compromise between two partly conflicting design criteria. It was desirable to make the twelve wires leading away from the recording site as short as possible in order to minimize capacitive cross-talk i.e. the preamplifiers had to be as close as possible to the recording site. On the other hand the preamplifiers had to be accommodated at a sufficient distance from the operative field not to obstruct the experimenter's vision.

C. Insertion of the electrode array into scala tympani

The alignment of wires was checked under the Zeiss otoscope before insertion of the tip of the electrode array into scala tympani. During the course of three to four experiments usually small pieces of polystyrene broke away from the tip of the array causing an irregular spacing of electrode terminals. By carefully cutting the tip of the array with a pair of scissors it was possible to use the remaining intact part of the array for further experiments. In this way the same array could be used for about ten successive experiments.

For the placement of the array in scala

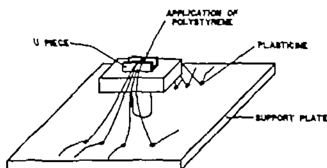

Fig 2.2 Schematic drawing of the wire assembly arrangement.

the longitudinal distribution of the CM response. The individual electrodes composing the probe were made of the same 50 μ stainless steel wire which was used in the single electrode technique Steel wires, about 150 mm long were slowly drawn through a bath of Bakelite Insulating Lacquer The coat so formed was then baked for not less than 20 min in an oven at 180 C. Wires were given at least three coats.

Twelve insulated wires were assembled side by side in a single plane and they were bonded together with polystyrene The assemblage was carried out under visual control (Zeiss otoscope) In order to achieve an accurate alignment of the electrodes in a single plane the wires were pulled over the edges of a U-shaped piece of metal. A schematic drawing of the simple assembly arrangement is given in Fig 2.2. The procedure began by tightly pulling the first insulated wire over the U-piece and fixing the wire ends on the 'support plate with plasticine The second wire was arranged in the same way close to the first one With a paint brush a small droplet of a polystyrene benzene solution was spread along the electrode wires over a length of about 15 mm Due to the surface tension of the liquid the wires were pulled close together The polystyrene dried rapidly and fixed the wires Then the third electrode was bonded to the second one and the manipulation was repeated until all twelve electrode wires were glued together In the event that any particular wire within the set was not aligned properly a small drop of benzene was applied so that the polystyrene softened locally This made a realignment of the wire possible

The distance between adjacent electrode wires was mainly determined by the blob-like thickenings of the insulation coating along the wires. It was possible to achieve a regular spacing of electrode wires in the array by carefully selecting wires with approximately equal blob sizes. Thus the distance between the centres of adjacent electrodes varied from about 150 to 180 μ Since the electrode diameter was 50 μ this variation in distance was considered tolerable.

B. Mounting of the electrode array

One end of the assembly of wires was trimmed with scissors and the completed ribbon like array was then mounted on the electrode probe carrier (see Fig 2.3 A) A rectangular piece of ordinary film tape was glued to the small metal lip sticking out of the carrier shaft The electrode array was bonded with Eastman adhesive 910 to this flexible tape support in such a way that about 8 mm of the ribbon-like array protruded beyond the support A schematic drawing of this arrangement is given in Fig. 2.3 B The free ends of the electrode wires were embedded with polystyrene in twelve grooves cut lengthwise into the round shaft of the carrier Finally after scraping off the insulation from the terminal section with a scalpel the electrode wires were soldered to twelve small steel bars permanently attached to the upper end of the carrier The carrier was made of heat resisting Teflon to avoid melting of carrier material during soldering

The carrier was then connected to the main part of the array holding unit (see Fig 2.4). This part consisted of a round perspex shaft with twelve permanently embedded steel wires leading to twelve preamplifiers arranged at the top end of the shaft. A short cylindrical piece of perspex was inserted between the probe

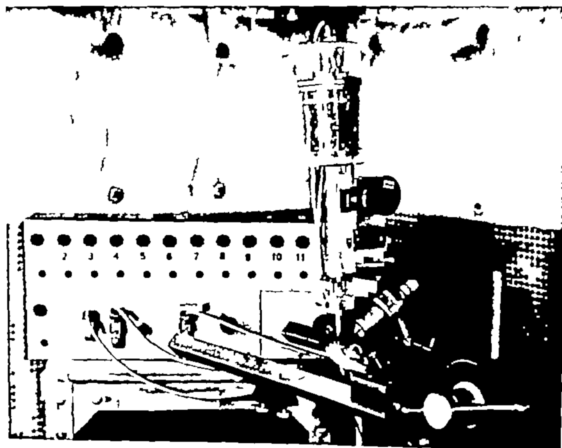

Fig. 2.5. Photograph showing the electrode array holding unit in the experimental position on the stereotaxic instrument. The array tip is inserted into the basal scala tympani of the right cochlea in the guinea pig skull. The holding unit is coupled via the ball joint to manipulator II. Preamplifiers on the holding unit are connected to the twelve main amplifiers contained in the box, shown in the background. The screened condenser earphone with the short metal tube for the acoustic coupling is displayed next to the guinea pig skull.

ELECTRICAL PROPERTIES OF THE ELECTRODE CHANNELS

It was essential for the faithful measurement of the CM distribution in the basal scala tympani that all data channels had identical electrical characteristics. In Fig. 2.7 one such channel is shown schematically representative for the whole set of the twelve parallel channels. The electrode wire was a.c.-coupled to the preamplifier. (Both a.c.-coupler and preamplifier were attached to the array holder.) The preamplifier was connected with a cable to the main amplifier stage contained in a separate box. The preamplifier in series with the main amplifier formed the 'channel amplifier'.

Recordings were taken between the sensing electrodes in scala tympani and an indifferent electrode on the animals neck. Hence the 'internal impedance' of the signal source was the sum of two components. The one component was the impedance between the basal scala tympani and animal earth which according to von Békésy (1960 *a*, p. 659) had a value of about 8 kΩ. The other component was the impedance at the electrode-perilymph interface. (The insulation coating was absent only at the cross section of the tip of the steel electrode.) This impedance amounted to ap-

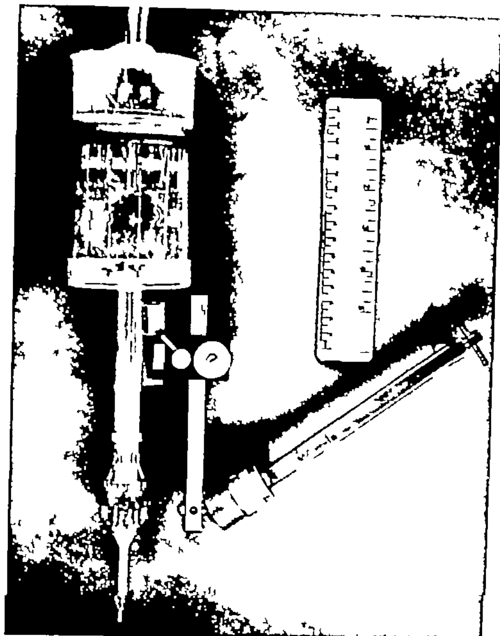

Fig 2 4 Photograph of the electrode array holding unit and preamplifiers. The small, ribbon-like electrode array is shown at the tip of the unit. The holding unit is mounted on manipulator I which in turn is coupled via the ball joint link (shown in the photograph) to manipulator II (shown in Fig. 2.5)

tympani a combination of two micromanipulators was employed (see Fig 2.4 and Fig 2.5) Manipulator I was coupled to manipulator II via a ball and socket joint this gave sufficient freedom of movement to manoeuvre the array tip into scala tympani through the narrow slit in the cochlear wall. The main shaft of the array holding unit was screwed to manipulator I With the ball joint unlocked manipulator I was tilted in such a way that the electrode array tip was in line with the slit in the basal turn Then the ball joint was locked and the electrode array position was adjusted in the lateral directions with manipulator II Finally the array was driven into scala tympani with manipulators I and II

D Channel connections in the single-electrode technique

In the single-electrode technique all electrodes were mounted in a perspex block (see Fig 2.6) With short leads connection was made to the a.c.-coupler attached to the main shaft of the array holding unit. Thus in both techniques the same channel amplifiers were employed for the recording of potentials.

fier channels. Second, since all channel amplifiers were fed from the same power supply there was a possibility of a channel interaction via the internal impedance of the power supply. This problem was solved by choosing a power supply unit with a small internal impedance.

Channel interaction was determined by inserting a test signal into one data channel and measuring the response in the idle adjacent channels. It turned out that the channel interaction could be considered negligible for our purposes. The response in the idle channels was maximally only about 1 to 1.5% of the response in the test channel and this was at the highest frequency employed in the study (20 kHz).

SOUND GENERATING EQUIPMENT

The stimulus signal was derived from two Solartron oscillators (Type CO 546) each of which was equipped with an attenuator covering a range of 60 db. The signal was fed via a 600Ω adaptor to the microphone amplifier. The latter was built in this laboratory. It had a flat frequency response from 100 Hz to 30 kHz and a gain factor of 29. Its linear dynamic range extended up to an output voltage of about 55 V rms. The output of the microphone amplifier was connected to the one-inch condenser microphone (Bruel & Kjaer 4132) which was used in the experiments as earphone, i.e. as electro-acoustic transducer. The voltage (190 V d.c.) for the polarization of the condenser microphone was supplied by the microphone amplifier.

The acoustic output of the one-inch condenser microphone was coupled via a short piece of metal tubing (length 15 mm) to the guinea pig's external ear. The transducer was carefully screened in order to prevent direct pick-up of the stimulus signal by the recording electrodes.

The calibration of the sound equipment was executed by monitoring the sound pressure in front of the eardrum with the aid of a calibrated sensing probe connected to a half-inch condenser microphone (Bruel & Kjaer 4134). The output of the sensing microphone was fed to a Bruel & Kjaer Microphone Amplifier Type 2604. It was found from this measurement that the sound generating system had a reasonably flat frequency response. Thus, there was an SPL at the eardrum of 90 ± 3 db from 200 Hz to 10 kHz for an oscillator output of 4 V rms and an attenuator setting of 25 db. The SPL had a value of 100 ± 5 db in the frequency range from 10 kHz to 70 kHz. (The standard reference level for the sound pressure is 0.0002 dynes per cm^2.)

The condenser microphone introduced quadratic distortion so that the second harmonic of the stimulus frequency appeared in the acoustic signal. However, this effect could be neglected in the present study since the second harmonic was smaller than the actual signal by 40 db at stimulus intensities usually employed (80 to 90 db SPL).

RECORDING

The block diagram of the recording system is shown in Fig. 2.8. The input, output and reference channels are marked differently for reasons of clarity.

The animal was placed in a shielded, soundproofed room. A sinusoidal stimulus from oscillator O_1 was applied to the guinea pig's ear by closing push-button switch S. (In two-tone interaction and overstimulation studies oscillator O_2 was used as well.) The resulting CM responses were amplified by the twelve a.c.-coupled channel amplifiers. By means of switch S_2 a particular output channel was selected. The output was then fed through a B & K amplifier and 1/3 octave filter (Bruel & Kjaer Microphone Amplifier Type 2604, Bruel & Kjaer Band-Pass Filter Type 1612). The unfiltered output could be directly displayed on a dual-beam oscilloscope (Tektronix Type 502 A) for inspection of the waveform of the CM.

For a given stimulus all twelve outputs were measured, one at a time. The amplitude of the

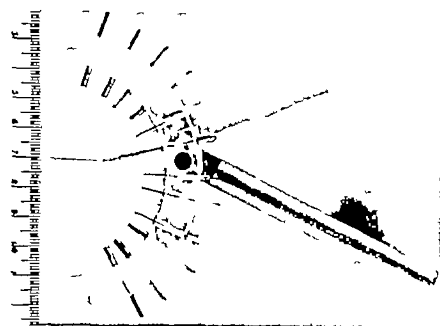

Fig 2.6 Photograph of the ring-shaped perspex block for the *mounting of* electrodes in the single electrode technique. The handle of the electrode wire (shown in the inside of the ring) is pushed into the complementary brass cylinder embedded in the block. The electrode wire thus mounted is then connected with a lead (shown on the outside of the ring) to a channel amplifier (scale division in mm)

proximately 30 kΩ. Due to the high input resistance of the preamplifiers (22 MΩ) there was no danger that slight differences in the internal impedance of the twelve channel sources would distort the measurement of the CM pattern. In addition the high input resistance of the preamplifiers served a further purpose. It was important not to introduce with the sensing equipment current loops of high conductivity which could alter the conductivity pattern present in the cochlea. The high input impedance of the data channels prevented such a disturbance of the current distribution in scala tympani.

All twelve transistorized amplifiers were built identically and they had the same flat frequency response from 0 to 20 kHz. The 3 db cut-off frequency was 40 kHz. Since electrodes were a.c.-coupled to the amplifiers a lower 3 db cut-off frequency of about 10 Hz was introduced. Thus over the frequency range (500 Hz to 20 kHz) used in the study the frequency response of the amplifiers was flat. The gain factor of the channel amplifiers was set at 500. However despite careful adjustment there remained a slight difference of maximally 2% between the gain factors of different channels.

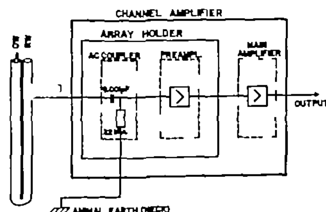

Fig 2.7 Block diagram of one channel amplifier representative for all twelve channel amplifiers. (The schematic drawing on the left shows the twelve electrodes of the array inserted into scala tympani, *RW* = round window *OW* = oval window)

A problem of major concern in the design and construction of electrode channels was the minimization of channel interaction. Only in the case of negligible interaction would channel outputs represent a replica of the original potential distribution in the cochlea. There were two potential sources of significant electrical interaction of the individual channels. First there was the interaction due to capacitive cross-talk. Its influence was kept at a minimum by making the wires from the recording site to the preamplifiers as short as possible and by screening the individual ampli

fier channels. Second, since all channel amplifiers were fed from the same power supply there was a possibility of a channel interaction via the internal impedance of the power supply. This problem was solved by choosing a power supply unit with a small internal impedance.

Channel interaction was determined by inserting a test signal into one data channel and measuring the response in the idle adjacent channels. It turned out that the channel interaction could be considered negligible for our purposes. The response in the idle channels was maximally only about 1 to 1.5% of the response in the test channel and this was at the highest frequency employed in the study (20 kHz).

SOUND GENERATING EQUIPMENT

The stimulus signal was derived from two Solartron oscillators (Type CO 546) each of which was equipped with an attenuator covering a range of 60 db. The signal was fed via a 600Ω adaptor to the microphone amplifier. The latter was built in this laboratory. It had a flat frequency response from 100 Hz to 30 kHz and a gain factor of 29. Its linear dynamic range extended up to an output voltage of about 55 V rms. The output of the microphone amplifier was connected to the one-inch condenser microphone (Bruel & Kjaer 4132) which was used in the experiments as earphone, i.e. as electro-acoustic transducer. The voltage (190 V d.c.) for the polarization of the condenser microphone was supplied by the microphone amplifier.

The acoustic output of the one-inch condenser microphone was coupled via a short piece of metal tubing (length 15 mm) to the guinea pig's external ear. The transducer was carefully screened in order to prevent direct pick-up of the stimulus signal by the recording electrodes.

The calibration of the sound equipment was executed by monitoring the sound pressure in front of the eardrum with the aid of a calibrated sensing probe connected to a half-inch condenser microphone (Bruel & Kjaer 4134). The output of the sensing microphone was fed to a Bruel & Kjaer Microphone Amplifier Type 2604. It was found from this measurement that the sound generating system had a reasonably flat frequency response. Thus, there was an SPL at the eardrum of 90 ± 3 db from 200 Hz to 10 kHz for an oscillator output of 4 V rms and an attenuator setting of 25 db. The SPL had a value of 100 ± 5 db in the frequency range from 10 kHz to 20 kHz. (The standard reference level for the sound pressure is 0.0002 dynes per cm^2.)

The condenser microphone introduced quadratic distortion so that the second harmonic of the stimulus frequency appeared in the acoustic signal. However, this effect could be neglected in the present study since the second harmonic was smaller than the actual signal by 40 db at stimulus intensities usually employed (80 to 90 db SPL).

RECORDING

The block diagram of the recording system is shown in Fig. 2.8. The input, output and reference channels are marked differently for reasons of clarity.

The animal was placed in a shielded, sound-proofed room. A sinusoidal stimulus from oscillator O was applied to the guinea pig's ear by closing push-button switch S. (In two-tone interaction and overstimulation studies oscillator O_2 was used as well.) The resulting CM responses were amplified by the twelve a.c.-coupled channel amplifiers. By means of switch S_1 a particular output channel was selected. The output was then fed through a B & K amplifier and 1/3 octave filter (Bruel & Kjaer Microphone Amplifier Type 2604, Bruel & Kjaer Band-Pass Filter Type 1612). The unfiltered output could be directly displayed on a dual-beam oscilloscope (Tektronix Type 502 A) for inspection of the waveform of the CM.

For a given stimulus all twelve outputs were measured, one at a time. The amplitude of the

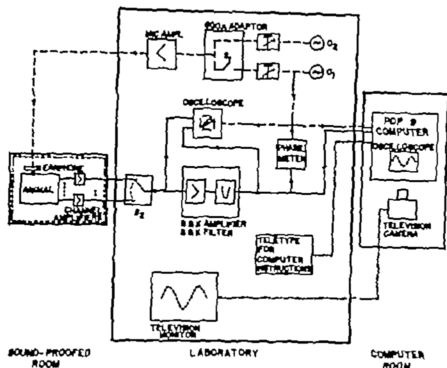

Fig. 2.8 Block diagram of the experimental set-up. - - - stimulus signal —— CM output signal — reference signal (from stimulus); —·— Computer instructions and television link.

filtered CM response was read from the monitor of the B & K amplifier. The phase was determined in one of two ways. Feeding the output from the B & K amplifier into the oscilloscope together with the stimulus signal and displaying the Lissajous figures was one possibility. In the other more accurate method a phase meter was employed. It measured the phase difference between the stimulus and the output signal. The meter was built in this laboratory according to a circuit diagram published by Woodbury (1961). The accuracy of the meter was ±2 over the frequency range used in the experiments.

For the graphical representation of the CM patterns the phase of the most basal electrode was taken as zero reference phase. This was achieved simply by subtracting from all twelve phase readings the value measured for the most basal electrode.

An alternative method was adopted when it became necessary to measure the CM response at low SPLs (40 to 60 db). The output signals were too small and the noise in the recording system was too high for the previously described methods to work satisfactorily. The recovery of the waveform of the output signal from noise was accomplished with the aid of a digital computer PDP-9 situated in the computer room. The scheme for the computer aided measurements was devised by my colleague H. F. Ross, who also wrote the computer programme. The method was based on the technique known as signal averaging. The noisy signal was recurrently sampled at 50 successive points. The sampling points were so spaced in time as to cover one to two periods of the signal waveform. Sampling was initiated by pulses derived from the zero-crossings of the reference signal which was provided by oscillator O_1. Corresponding samples from recurrent sweeps were added up thus reinforcing the periodic signal waveform at each repetition. The signal waveform was displayed on the oscilloscope screen of the computer. From there it was transmitted via a television link back to the laboratory. In this way it was possible to observe the building up of the waveform of the output signal on the television screen during tonal stimulation. The stimulus to the animal was turned off (by opening switch S_1) as soon as the waveform of the output showed a satisfactory sinusoidal shape of sufficient amplitude. For any given stimulus

Fig. 2.9 Example of a computer print out. (The data are drawn in Fig. 3.1.A, see 14.5 kHz record).
Key: Row 1 Record 21 –30 db (corresponds to 85 db SPL), 14.50 kHz. Column 1 electrode numbers 1 to 12; 2 sine (electrode output); 3 cosine (electrode output); 4 CM amplitude in μV rms, 5 $\log_{10}$ CM amplitude 6, CM phase referred to phase value of electrode 1, 7 CM phase measured against stimulus signal.

all twelve electrode outputs were recovered in this way Then the computer data were stored on magnetic tape

This technique allowed the rapid collection of data. During a session of three to four hours the responses due to about 80 different stimuli could be measured. In terms of the previously employed techniques this meant taking 80 × 12 × 2 = 1 920 different accurate amplitude and phase readings—quite an impossible task even if there had not been any noise.

After the data collecting phase sinusoidal curves were fitted to the data stored on the magnetic tape and subsequently the computer printed out amplitude and phase values. (Here also the phase difference was measured between the reference signal (stimulus) and the output signal.) An example of such a print-out is given in Fig. 2.9

Since the cables leading from the laboratory to the computer room were quite long there was cross-talk from the reference channel) to the signal channel. The 'ghost signal' in the signal channel due to cross-talk had a magnitude corresponding to a CM amplitude of 0.05 to 0.5 μV rms. In cases where the CM had a value in the region of 2 to 5 μV rms the ghost signal was measured separately and later subtracted from the compound signal. The ghost signal was determined by measuring the response in the idle signal channel, i.e. with no CM signal applied.

DISCUSSION OF TECHNIQUE

It is expedient to discuss at this point some questions relevant to the application of the multi-electrode technique. There are basically two aspects which need consideration. The one aspect is concerned with the question whether the mechanical performance of the cochlear system is disturbed due to the slit opening and the insertion of the probe into scala tympani. The other aspect relates to the problem whether the mechanical presence of the array in the scala distorts the potential field set up by hair-cell activity

According to Johnstone & Boyle (1967) the fluid level in scala tympani has negligible influence on the mechanical response of the basal part of the basilar membrane thus there was no difference in their results whether the perilymph was present or absent in the basal scala tympani (provided the basilar membrane was not dried out. Johnstone 1969). This is consistent with von Békésy's observations (1960 *a*, p. 439) on dimensional models where the emptying of 'scala tympani' did not alter the position of the vibratory pattern manifested by the local stability of the circular eddy in 'scala vestibuli. Further evidence for the negligible effect of slit-like openings in the cochlear wall on the excitation pattern comes from the experiments by Tasaki et al. (1952). These authors made a small opening in the

wall of scala vestibuli in the second turn of the guinea pig s cochlea and they monitored the CM response in the third turn before and after the manufacture of the hole Due to the hole the CM response dropped only by an amount of 3 to 4 db (Tasaki et al came to the very interesting conclusion that a considerable portion of the acoustic energy must be transmitted to the upper parts of the cochlea by means of longitudinal coupling in the mem brane This is important since mathematical models of cochlear hydrodynamics usually neg lect coupling forces between the transverse ele ments of the basilar membrane (see Zwislocki, 1953) It is difficult to judge whether the hole produced a complete release of the pressure wave in the fluid column of scala vestibuli and therefore prevented energy transport via the fluid medium to the regions apical to the hole. If this was the case the conclusion of Tasaki et al. would be necessary Despite the fact that the hole had an area almost as large as the canal cross section it would probably be more realistic to visualize the effect of the hole as that of a hydraulic filter' with fre quency dependent characteristics. On the basis of this assumption one would predict the oc currence of a large attenuation of the apical signal in cases where the wavelength of the pressure wave approaches the dimensions of the hole i e at high frequencies where the wavelength is sufficiently short. Tasaki et al. reported that 'for all the frequencies' employed the drop in potential in the third turn was the same However in the case of a hole (width 200 μ) connecting the basal scala vestibuli with the scala tympani of the second turn they recorded an equal change of the apical poten tial 'for frequencies below 800 Hz this we may assume could mean that at higher fre quencies apical potentials were relatively more affected. The problem of which medium—the membrane or the fluid—is mainly responsible for the energy transport is extremely difficult to solve with experiments like those of Tasaki et al. Not only can an opening influence the hydrodynamics of the system but it can also influence the recording situation, due to the outflow of perilymph from the opening there exists the possibility of electrical cross-con nections between channels via the electrode holes. Clearly the necessity to keep these two effects separate seriously narrows the range of possible spatial configurations of electrode positions and opening positions.)

Evidence for the negligible influence of the slit in the wall of the basal scala tympani on the functioning of the cochlea is provided by the present study Fig 2.10 shows the CM amplitude patterns obtained from two different guinea pigs for the same stimulus parameters. The one curve was measured with the single electrode technique i.e. ten electrodes were essentially sealed into the holes in the wall of scala tympani The other curve was recorded with the multi-electrode technique, i e. the electrode array was inserted through the slit into scala tympani It can be seen that both techniques produced the same result.

The weight of the evidence mentioned so far seems to support the view that the effect of the opening in the basal part of scala tympani can be neglected. However there is a statement in the literature (von Békésy & Rosenblith, 1951 p 1105 von Békésy 1960 b p. 92) that a circular eddy occurs at any opening in the cochlear wall under strong tonal stimulation. It is stated further that covering the opening with a glass plate and immersing the whole preparation in fluid reduces the eddy to a great extent. In our experiments a considerable amount of perilymph was allowed to collect above the slit opening. Whether this fluid column above scala tym pani had an effect similar to that of the meas ures taken by von Békésy is, of course impos sible to decide on the basis of CM recordings.

A further point concerns the fact that the array tip was inserted into scala tympani so that a mechanical object was present in the tympanic channel. This situation is similar to some extent to the model study of von Békésy (1960 a p 437) where a small object was placed in scala tympani' Von Békésy observed

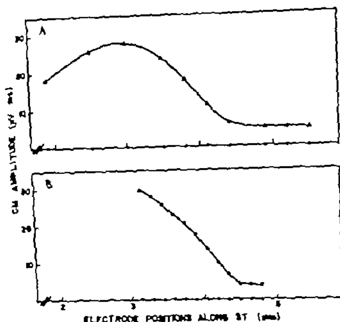

Fig. 2.10. CM amplitude pattern at 12 kHz, 90 db SPL, measured in two different *guinea pigs*. (Electrode position along scala tympani, *ST* is given.)

(*A*) Pattern obtained with the 'single electrode' technique (ten different electrodes).

(*B*) Pattern obtained with the 'multi-electrode' technique. The two different techniques gave the same results over the region studied.

a distortion of the eddy in scala tympani however the eddy in 'scala vestibuli' remained unchanged. This effect seemed to be related to the narrowing of 'scala tympani' due to the presence of the object and von Békésy concluded 'that nature had made the depth of the duct as small as possible without going so far as to cause a spreading out of the vibratory pattern along the cochlear partition. Since in our experiments there was *sufficient free space* between the actual array *and* the borders of the slit *one would assume that the* array did *not effectively narrow* the canal.

The other major question which needs consideration is concerned with the influence the mechanical presence of the array might have on the potential field in the scala. As shown in Fig. 2.10, both techniques employed in the study with their very different electrode arrangements gave the same results, hence it seems very unlikely that the array *probe* significantly distorts the potential field. In Fig. 2.11 A. the results from another *test experi*ment are displayed. The CM potentials were measured for the same *stimulus* at *two* different depths of insertion of the probe into scala tympani. Thus the length of the array tip inserted in the scala was different for the two measurements. There are only very slight differences between the patterns acquired from different depths and we may assume that these differences are due to the conductive *proper*ties of the inner ear rather than *the different* lengths with which the array projects into the scala. *Yet another piece of evidence* is illustrated in Fig. 2.11 B. Here the CM pattern of an 8 kHz tone was registered. (The animal was exposed previously to a traumatic tone of 13 kHz; this explains the peculiar shape of the pattern. See Section 3. Tonal Overstimulation.) This pattern was chosen *for the test experi*ment because there was a large *phase shift* between electrodes 5 *and* 6. The array was translated by a *small amount* in the longitudinal direction and the CM response to the same *stimulus* was measured again. As shown in the illustration we obtained essentially the same pattern, displaced however in the longitudinal direction. The large phase shift occurs now between electrodes 3 and 4. This is convincing evidence that the electrode probe itself has practically no influence on the results and can be regarded as a 'passive' sensing device meeting the purpose for which it was designed.

wall of scala vestibuli in the second turn of the guinea pig's cochlea and they monitored the CM response in the third turn before and after the manufacture of the hole. Due to the hole the CM response dropped only by an amount of 3 to 4 db (Tasaki et al. came to the very interesting conclusion that a considerable portion of the acoustic energy must be transmitted to the upper parts of the cochlea by means of longitudinal coupling in the membrane. This is important since mathematical models of cochlear hydrodynamics usually neglect coupling forces between the transverse elements of the basilar membrane (see Zwislocki, 1953). It is difficult to judge whether the hole produced a complete release of the pressure wave in the fluid column of scala vestibuli and therefore prevented energy transport via the fluid medium to the regions apical to the hole. If this was the case the conclusion of Tasaki et al. would be necessary. Despite the fact that the hole had an area almost as large as the canal cross section it would probably be more realistic to visualize the effect of the hole as that of a hydraulic filter with frequency dependent characteristics. On the basis of this assumption one would predict the occurrence of a large attenuation of the apical signal in cases where the wavelength of the pressure wave approaches the dimensions of the hole, i.e. at high frequencies where the wavelength is sufficiently short. Tasaki et al. reported that 'for all the frequencies employed the drop in potential in the third turn was the same. However, in the case of a hole (width 200 μ) connecting the basal scala vestibuli with the scala tympani of the second turn they recorded an equal change of the apical potential for frequencies below 800 Hz' this, we may assume, could mean that at higher frequencies apical potentials were relatively more affected. The problem of which medium—the membrane or the fluid—is mainly responsible for the energy transport is extremely difficult to solve with experiments like those of Tasaki et al. Not only can an opening influence the hydrodynamics of the system but it can also influence the recording situation due to the outflow of perilymph from the opening there exists the possibility of electrical cross-connections between channels via the electrode holes. Clearly the necessity to keep these two effects separate seriously narrows the range of possible spatial configurations of electrode positions and opening positions.)

Evidence for the negligible influence of the slit in the wall of the basal scala tympani on the functioning of the cochlea is provided by the present study. Fig. 2.10 shows the CM amplitude patterns obtained from two different guinea pigs for the same stimulus parameters. The one curve was measured with the single electrode technique, i.e. ten electrodes were essentially sealed into the holes in the wall of scala tympani. The other curve was recorded with the multi-electrode technique, i.e. the electrode array was inserted through the slit into scala tympani. It can be seen that both techniques produced the same result.

The weight of the evidence mentioned so far seems to support the view that the effect of the opening in the basal part of scala tympani can be neglected. However, there is a statement in the literature (von Békésy & Rosenblith, 1951, p. 1105; von Békésy, 1960 *b*, p. 92) that a circular eddy occurs at any opening in the cochlear wall under strong tonal stimulation. It is stated further that covering the opening with a glass plate and immersing the whole preparation in fluid reduces the eddy to a great extent. In our experiments a considerable amount of perilymph was allowed to collect above the slit opening. Whether this fluid column above scala tympani had an effect similar to that of the measures taken by von Békésy is, of course, impossible to decide on the basis of CM recordings.

A further point concerns the fact that the array tip was inserted into scala tympani so that a mechanical object was present in the tympanic channel. This situation is similar to some extent to the model study of von Békésy (1960 *a*, p. 437) where a small object was placed in scala tympani. Von Békésy observed

pothesis to be tested by the experiments es the cochlear microphonic distribution he cochlear ducts as the spatially filtered of the hair-cell activity along the membrane.

$$) = \int_{-\infty}^{\infty} H(z)\, W(x-z)\, dz = H(x) * W(x) \quad (1)$$

ion (1) shows the connection between and CM(x) for any arbitrary auditory us. In our experiments sinusoidal stimuli used and we may adopt the trigonometric e alternative exponential notation to y $H(x)$

usoidal stimulation of the inner ear s travelling wave motion along the coch- partition. The mechanical excursions of artition activate the hair-cell generators. nay represent the electrical output of any unit generator situated at a point x_a the basilar membrane in terms of a ier series. For an external stimulus of an frequency w this series takes the form.

$$, t) = A_0(x_a) + \sum A\ (x_a) \cos (nwt \quad B_n(x_a)) \quad (2a)$$

expression (2 a) indicates that the electri- output at x_a may contain harmonic com- ents due to nonlinearities in the transducer em. Since the space variable x assumes all ies x_a along the basilar membrane $h(x, t)$ otes the spatial distribution of the electrical put along the membrane:

$$, t) = A_0(x) + \sum A_n(x) \cos (nwt - B_n(x)) \quad (2b)$$

when written in exponential form

$$h(x\ t) = A_0(x) + \sum^{\infty} \mathrm{Re}[A_n(x)\, e^{\ jB_n(x)}\, e^{jnwt}] \quad (2c)$$

We obtain the instantaneous distribution of electrical potentials along the cochlear scalae $cm(x\ t)$ by spatially filtering $h(x\ t)$:

$$cm(x, t) = \int_{-\infty}^{\infty} [A_0(z) + \sum_1^{\infty} \mathrm{Re} \times (A\ (z)\, e^{\ jB_n(z)}\, e^{jnwt})]\, W(x-z)\, dz \quad (3a)$$

The time-dependent factors in (3 a) are unaf fected by the spatial integration and we can write

$$cm(x, t) = \int_{-\infty}^{\infty} A_0(\ )\, W(x-z)\, dz + \sum_1^{\infty} \mathrm{Re} \left[e^{jnwt} \int_{-\infty}^{\infty} A\ (\ )\, e^{\ jB_n(z)}\, W(x-\ )\, dz \right]$$

with

$$\int_{-\infty}^{\infty} A_0(z)\, W(x-z)\, dz = Q_0(x)$$

$$\int_{-\infty}^{\infty} A_n(z)\, e^{\ jB_n(z)}\, W(x-z)\, dz = Q_n(x)\, e^{\ jP_n(x)}$$

it follows

$$cm(x, t) = Q_0(x) + \sum_1^{\infty} \mathrm{Re}[Q_n(x)\, e^{\ jP_n(x)}\, e^{jnwt}]$$

$$cm(x, t) = Q_0(x) + \sum^{\infty} Q_n(x) \cos (nwt - P_n(x)) \quad (3b)$$

With a set of sensing electrodes placed along the cochlear duct the potential distribution $cm(x\ t)$ can be recorded. By extracting the fundamental frequency of the electrode out puts we obtain the distribution of the funda- mental component.

$$cm(x, t) = Q_1(x) \cos (wt - P_1(x)) \quad (4)$$

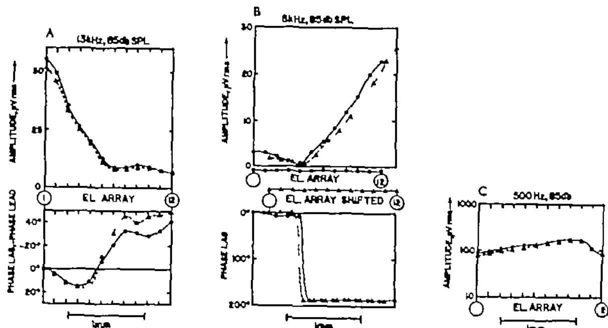

Fig 2 11 (A) CM amplitude and phase pattern at 13 kHz, 85 db SPL. The array was inserted to a depth of 400 μ (●—●) and 300 μ (▲—▲) into scala tympani. There is very little difference between the CM patterns measured at different depths.

(B) CM amplitude and phase pattern at 8 kHz, 85 db SPL (after overstimulation with a tone of 13 kHz, 130 db for 3 min). The electrode array was translated in the apical direction by approximately 700 μ and essentially the same CM pattern was obtained. The large phase shift between electrodes 5 and 6 occurred after the translation between electrodes 3 and 4 ●—● Pattern before translation ▲—▲ pattern after translation.

(C) CM amplitude patterns obtained from two different guinea pigs for the same stimulus (500 Hz, 85 db SPL). The two curves are almost identical ●—● first guinea pig. ▲—▲ second guinea pig. In (A) (B), (C) electrodes are numbered from 1 to 12 beginning with the most basal electrode.

Additional support for the validity of the CM recordings taken with the electrode array derives from the fact that each of the twelve electrode outputs had exactly the same properties as the CM recorded in the normal way by other workers with only one or two electrodes in the basal turn This concerns the magnitude of the potentials and the intensity function It suggests that the slit technique does not disturb the system more than the traditional technique with only a few small holes.

Theoretically speaking the multi-electrode technique cannot itself provide the answer to the question whether it causes disturbance in the cochlear system since such an answer requires the knowledge of the CM distribution in the completely undisturbed cochlea for comparison The evidence presented above strongly suggests a negligible interference of the technique with the functions of the cochlea but even if there was interference the technique would still be useful provided the interference was stable from experiment to experiment The question of reproducibility of results was one of major concern in this study since any uncontrolled variability in the CM patterns would make the quantitative investigation of the spatial filter effect completely impossible. The great pains taken both with the surgery and the equipment to set up the experiment proved worth while in the long run In Fig 2.11 C two CM amplitude patterns from different guinea pigs are shown for the same stimulus parameters It can be seen that the curves are almost identical Thus experiments yielded reproducible data.

a feature observed in the majority of the preparations. The drop in potential is probably an artefact due to the strong curvature of the basilar membrane and the scala tympani in this region. Electrode tips are arranged in the array in a straight line which approximates to the curved course of the cochlear partition and cochlear canals over a short distance only. In terms of the array configuration the cochlear canals take a sharp bend away from the array in the region of electrodes 11 and 12. Thus 11 and 12 are the electrodes dislocated most from the 'ideal' line following the longitudinal course of the membrane. It can be seen in the 500 Hz record that there is practically no alteration in the phase pattern at 11 and 12. This also indicates that the drop in amplitude at 11 and 12 is due to the placement of the array rather than phase cancellation. This conclusion results from the fact that in all high frequency records—where phase cancellation is manifest—amplitude variations are always accompanied by marked phase variations.

The goodness of a preparation may be judged on the basis of low frequency records because the expected patterns are simple and deviations from the normal response stand out clearly enough to allow rapid judgement. However, with the experience accumulated over many experiments it was possible to estimate the quality of preparations by considering the CM pattern at any frequency between 500 Hz and 15 kHz.

CM patterns take a more complicated form as the stimulus frequency is increased. The maximum of the excitation pattern along the membrane moves progressively towards the basal end of the cochlea with increasing frequency, the wavelengths of the excitation pattern become progressively shorter and this means that the phase lag gradient (phase change per unit length) along the partition increases with frequency. Closely neighbouring hair-cells are driven out of phase and consequently there will be negative interference, mutual cancellation of hair-cell outputs in the surrounding liquid spaces. The total number of hair-cells activated is probably smaller at high frequencies than at low ones because the excitation pattern is confined to a relatively shorter length of membrane. The general tendency of the CM amplitude to decrease when the stimulus frequency is raised can be read from Fig. 3.3.A. This tendency is probably due to the combined effect of the reduction in the number of activated hair-cells and the growing influence of phase cancellation with increasing frequency.

The CM amplitude distributions undergo characteristic changes with increasing stimulus frequency. Electrodes in the distant part of the array show relatively more drop in potential than do the proximal electrodes. The low level of the distant amplitudes is maintained when 15 kHz is exceeded and this observation indicates that the bulk of the excitation occurs in the region basal to this part of the array, that is at frequencies beyond 15 kHz. The most interesting feature, however, is the occurrence of a distinct amplitude minimum, well shown in the records at frequencies around 14 kHz.

The CM phase gradient along the array increases progressively with stimulus frequency (as shown in the records from 500 Hz to 12 kHz), thus at 12 kHz there is an overall phase difference between electrodes 1 and 12 of 196°. In the 13.5 kHz record this phase difference amounts to 258°, however the shape of the CM phase distribution is clearly different from that in the 12 kHz record. The phase gradient is small in the proximal and distal parts of the array while it is large in the region of the amplitude minimum. The co-occurrence of an amplitude minimum and a large phase gradient is a characteristic property of CM patterns at high frequencies, in the present example at frequencies around 13.5 kHz.

At 13.75 kHz the phase gradient in the region of the amplitude minimum is even greater than at 13.5 kHz. The phase difference between electrodes 6 and 7 has a value of 143°. Clearly this is an enormous local varia-

The amplitude distribution $Q_1(x)$ and the phase distribution $P_1(x)$ define the spatial distribution of the fundamental component of the cochlear microphonic. Both parameter distributions can be determined experimentally by measuring the amplitude and phase values of all electrode outputs.

Since we are only interested in the amplitude and phase distributions it is preferable to use the exponential instead of the trigonometric notation It is permissible to omit the time variable because it does not enter calculations. It therefore suffices to write

$$CM_1(x) = \int_{-\infty}^{\infty} H_1(x)\, W(x-z)\, dz = H_1(x) * W(x) \quad (5)$$

$$CM_1(x) = Q_1(x)\, e^{\,jP_1(x)} \quad (5\,a)$$

$$H_1(x) = A_1(x)\, e^{\,jB_1(x)} \quad (5\,b)$$

The expressions in (5 *a*) and 5 *b*) show the essential parameter distributions involved in the *spatial filtering operation* The amplitude and phase distributions of the cochlear microphonic are related to the amplitude and phase distributions of the hair-cell outputs according to equation (5) Multiplication of equation (5) with a constant reference phase factor exp(jP) has no influence on the spatial integration. It is therefore permissible to refer the phase readings of the electrode outputs to any arbitrary phase value In the following diagrams the output phases are always referred to the phase value of the most basal electrode. Since in our experiments we exclusively considered the fundamental component of the cochlear microphonic we may simplify the notation in the text. Thus, with $H(x)$ we mean the spatial distribution of the fundamental component of the hair-cell outputs in response to sinusoidal stimuli $CM(x)$ or $CM(x_e)$ denotes the longitudinal distribution of the fundamental component of the cochlear microphonic in response to sinusoidal stimuli

All CM patterns displayed in this section were obtained with the multi-electrode array The most basal electrode of the array was always located in the region of 3 to 3.5 mm, measuring from the basal end of the basilar membrane. In the graphs the space coordinate is indicated by the electrode positions (see Fig 3 1.B) It is expedient for the discussion of the CM patterns to express the space coordinate in terms of electrode numbers. Thus the electrodes of the array are numbered from **1** to **12** beginning with the most basal electrode

A. THE DESCRIPTION OF DATA

CM amplitude and phase patterns

Experiments were carried out by measuring the amplitude and phase distribution of the CM along the electrode array for tonal stimuli of different frequencies. In all experiments we obtained response patterns with the same basic properties, all characteristic features of the distributions being reproducible in different guinea pigs.

Fig. 3 1.A shows a typical example of a set of CM patterns from one guinea pig the patterns were measured at frequencies from 500 Hz to 15.5 kHz and a constant SPL of 85 db The low frequency (500 Hz) record can be used as a control of the preparation and the uniformity of the sensing electrodes. At this frequency all individual electrodes composing the array are essentially equidistant from the maximum excitation which occurs in the apical portion of the cochlea. The wave length in the basal part of the excitation pattern is very long compared to the array width and we may therefore expect very little phase variation along the array This expectation is confirmed by the 500 Hz record which shows negligible phase change between electrodes Due to the long wavelength of the excitation pattern there is practically no phase cancellation in the region of the array and consequently the CM amplitude pattern has an appearance similar to that of the basal part of the envelope of the excitation pattern. Thus the amplitude in the 500 Hz pattern grows continuously in the apical direction However at electrodes **11** and **12** the amplitude declines,

a feature observed in the majority of the preparations. The drop in potential is probably an artefact due to the strong curvature of the basilar membrane and the scala tympani in this region. Electrode tips are arranged in the array in a straight line which approximates to the curved course of the cochlear partition and cochlear canals over a short distance only. In terms of the array configuration the cochlear canals take a sharp bend away from the array in the region of electrodes 11 and 12. Thus 11 and 12 are the electrodes dislocated most from the 'ideal' line following the longitudinal course of the membrane. It can be seen in the 500 Hz record that there is practically no alteration in the phase pattern at 11 and 12. This also indicates that the drop in amplitude at 11 and 12 is due to the placement of the array rather than phase cancellation. This conclusion results from the fact that in all high frequency records—where phase cancellation is manifest—amplitude variations are always accompanied by marked phase variations.

The goodness of a preparation may be judged on the basis of low frequency records because the expected patterns are simple and deviations from the normal response stand out clearly enough to allow rapid judgement. However with the experience accumulated over many experiments it was possible to estimate the quality of preparations by considering the CM pattern at any frequency between 500 Hz and 15 kHz.

CM patterns take a more complicated form as the stimulus frequency is increased. The maximum of the excitation pattern along the membrane moves progressively towards the basal end of the cochlea with increasing frequency the wavelengths of the excitation pattern become progressively shorter and this means that the phase lag gradient (phase change per unit length) along the partition increases with frequency. Closely neighbouring hair-cells are driven out of phase and consequently there will be negative interference mutual cancellation of hair-cell outputs in the surrounding liquid spaces. The total number of hair-cells activated is probably smaller at high frequencies than at low ones because the excitation pattern is confined to a relatively shorter length of membrane. The general tendency of the CM amplitude to decrease when the stimulus frequency is raised can be read from Fig. 3.1.A. This tendency is probably due to the combined effect of the reduction in the number of activated hair-cells and the growing influence of phase cancellation with increasing frequency.

The CM amplitude distributions undergo characteristic changes with increasing stimulus frequency. Electrodes in the distant part of the array show relatively more drop in potential than do the proximal electrodes. The low level of the distant amplitudes is maintained when 15 kHz is exceeded and this observation indicates that the bulk of the excitation occurs in the region basal to this part of the array that is at frequencies beyond 15 kHz. The most interesting feature, however is the occurrence of a distinct amplitude minimum, well shown in the records at frequencies around 14 kHz.

The CM phase gradient along the array increases progressively with stimulus frequency (as shown in the records from 500 Hz to 12 kHz), thus at 12 kHz there is an overall phase difference between electrodes 1 and 12 of 196 In the 13.5 kHz record this phase difference amounts to 258 however the shape of the CM phase distribution is clearly different from that in the 12 kHz record. The phase gradient is small in the proximal and distal parts of the array while it is large in the region of the amplitude minimum. The co-occurrence of an amplitude minimum and a large phase gradient is a characteristic property of CM patterns at high frequencies, in the present example at frequencies around 13.5 kHz.

At 13.75 kHz the phase gradient in the region of the amplitude minimum is even greater than at 13.5 kHz. The phase difference between electrodes 6 and 7 has a value of 143 Clearly this is an enormous local varia-

tion considering that the interelectrode distance is only 150 μ. The appearance of the phase pattern changes abruptly when the stimulus frequency exceeds 13 75 kHz. Thus at 14 kHz the distant part of the array definitely leads the proximal part in phase. This phase reversal in the CM pattern at high frequencies can only be observed by means of closely spaced electrodes. The technique of Tasaki et al. (1952) with only two recording points in the basal coil of the cochlea is completely inadequate for the study of the CM phase variation at high frequencies. The single electrode technique described in Section 2, with a minimum distance of 300 μ between electrodes was not good enough for the recording of complicated phase patterns like those displayed in the records from 14 kHz to 15 5 kHz. Comparison between the phase patterns at 15 kHz and at 15.5 kHz reveals a distinct shift of the zero-crossings, maxima and minima of the 15.5 kHz phase patterns by about one electrode distance in the basal direction The overall phase variation along the array decreases noticeably from 14.5 kHz to 15 5 kHz.

We may summarize those features of the CM patterns which are most important for the demonstration of the spatial filter effect. 1) Amplitude minima are always accompanied by large changes in phase between adjacent electrodes. 2) Phase reversal occurs at high stimulus frequencies and distant electrodes may lead proximal ones in phase

CM patterns in vector form

CM patterns represent complex functions of the real space variable x since they comprise two parameter distributions, those of amplitude and phase The two distributions may be plotted separately as shown in Fig 3 1 A, or they may be combined in a single 3-dimensional graph, with the dimensions of the graph given by a set of complex planes arranged along the space coordinate x This is because an electrode output at x can be visualized as a complex number or a vector in the complex plane at x with the amplitude and phase value of the electrode output representing the vector length and vector phase angle respectively Thus it is easy to imagine the CM distribution as a line connecting the endpoints of the output vectors in the complex planes at the electrode positions 1 to 12. However for the purposes of the present discussion it is sufficient to consider the projection of this line into a single complex plane, say the plane at electrode 1 We may conveniently call the projected version of the CM distribution the 'vector representation' or 'vector form' It is constructed by simply plotting all twelve output vectors in the same plane and by joining the vector endpoints through a trajectory (For completeness of the definition it may be mentioned that this trajectory denotes the projection of the complex CM distribution into a single plane.)

In Fig 3 2.A, B C the data from Fig 3 1 A are redrawn in vector form for the stimulus frequencies 13.5 13 75 and 14 kHz. Phase reversal occurs in this frequency region and the vectorial representation of data is best suited to illustrate this phenomenon. At 13.5 kHz the CM pattern exhibits progressive phase lag along the array from 1 to 12. By measuring the phase lag in the clockwise direction we obtain for the 13.5 kHz record a trajectory which encircles the origin of the vector plane Clearly any trajectory characterised by a progressive phase lag encircles the origin With increasing stimulus frequency the trajectory approaches and eventually crosses the origin After crossing phase reversal within the vector bundle must occur because the trajectory no longer encircles the origin. Thus in the 14 kHz record there is no encirclement of the origin, and it can be seen that the phase reverses between electrodes 5 and 6 electrode 6 leading in phase electrode 5

Vector representation of the data discloses the occurrence of the phase reversal with increasing frequency as the result of a simple continuous process. This is due to the fact that in this representation the CM amplitude

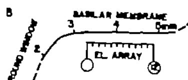

Fig. 3.1. (A) Typical example of a set of CM amplitude and phase patterns measured in one guinea pig. Note the co-occurrence of an amplitude minimum and large phase gradient in the 13.5 kHz and 13.75 kHz record. CM phase patterns beyond 13.75 kHz show phase reversal.

(B) Position of electrode array (*EL. ARRAY*) in relation to the length coordinate of the basilar membrane. —— amplitude; – – – phase.

and phase data are considered in combined vector form. If the phase pattern is considered alone, like in Fig. 3.1.A, the transition from the 13.75 kHz to the 14 kHz phase pattern appears to be an abrupt event, and therefore quite irritating to the observer.

A simple model can be given to explain the transition from a trajectory with progressive

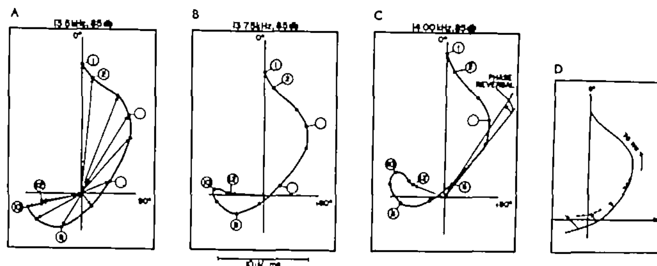

Fig 3.2 (A–C) Records (13.5 kHz, 13 75 kHz, 14 kHz) from Fig. 3 1.A redrawn in vector form. In (A) all output vectors are shown in (B) and (C) all vectors apart from 1 and 12 are omitted for clarity The trajectory connects all vector endpoints. Phase lag is counted in the clockwise direction The trajectory approaches with increasing frequency the origin of the vector plane note the concomitant increase in phase difference between 6 and 7 In (C) phase reversal occurs, 6 leading 5 in phase. In (A) and (B) the trajectory encircles the origin In (C) it does not.

(D) Artificially induced phase reversal by addition of small vector with large phase lag and amplitude which declines as the round window (*RW*) end of the array is approached.

phase lag (13 75 kHz) into one with phase reversal (14 kHz) This is illustrated in the schematic drawing of Fig 3 2.D Let us add to all electrode outputs in a pattern like the one at 13 75 kHz a small vector with a large phase lag and a length which declines as the basal end of the array is approached. The resulting trajectory has an appearance like the one at 14 kHz, i e it does not encircle the origin Something analogous to this vector addition may be expected to happen in reality As the stimulus frequency is increased from 13 75 to 14 kHz the wavelengths in the excitation pattern will shorten and a small group of distant hair-cells will be operating with slightly larger phase lag than before The influence of these distant hair-cell outputs is of course felt with an amplitude which declines towards the basal end of the array The model provides a qualitative explanation for the observed phase reversal and it suggests the far reaching influence of alterations in the outputs of subsets of hair-cell operators on the appearance of the whole CM pattern an influence postulated by the spatial filter hypothesis.

A further point which deserves to be mentioned concerns the situation where the trajectory actually crosses the origin This situation was thoroughly explored in a preparation where one electrode of the array recorded very nearly zero amplitude in the frequency region of the phase reversal Thus this electrode output, when plotted on the trajectory very nearly coincided with the origin of the vector plane. The output of this electrode was displayed on the oscilloscope screen and a faint sinusoidal signal was just noticeable in the background noise It was interesting to observe that the output signal was extremely unstable shifting abruptly back and forth by about 180 on the oscilloscope screen All other electrode outputs, however were perfectly stable This finding, although it may seem strange at first glance can be interpreted quite plausibly Consideration of Fig 3 2 shows that the phase difference between the adjacent electrodes 6 and 7 grows continuously when the trajectory approaches the origin When the trajectory crosses the origin this phase difference becomes approximately 180 Thus a point in the immediate vicinity of the origin, intermediate to 6 and 7 is framed by two vector bundles ap-

proximately 180° out of phase with each other. This situation may be visualized as an unstable equilibrium, any small disturbance causing the small intermediate vector to shift to either of the two bundles.

B THE ANALYSIS OF DATA

The spatial filter hypothesis is stated in the form of the convolution integral in equation (1):

$$CM(x) = H(x) * W(x) \tag{1}$$

For the demonstration of the spatial filter effect the following mathematical procedure was adopted. A certain hypothetical function $H(x)$ was assumed and subjected to the convolution in equation (1). The shape of $H(x)$ was chosen so as to resemble excitation patterns likely to exist in reality. The resulting hypothetical $CM(x)$ distribution was examined for properties similar to the ones found in the experimental data. In the event that a hypothetical $CM(x)$ closely approximated to a given real CM pattern it was further assumed that the corresponding hypothetical $H(x)$ approximated to the real hair-cell output pattern along the basilar membrane.

However, according to equation (1) $CM(x)$ depends on $H(x)$ and the weighting function $W(x)$ and consequently it is important to use in the mathematical analysis a function $W(x)$ based on experimental observations. Fortunately useful data about $W(x)$ are available in the literature.

The weighting function $W(x)$

The electrical attenuation properties of the cochlear ducts in the guinea pig were studied by four different investigators or groups of investigators (von Békésy, 1960 *a*; Tasaki & Fernández, 1952; Tasaki et al., 1952; Misrahy et al., 1958; Johnstone et al., 1966). All investigators agree that the longitudinal spread of current in the basal turn can be accurately described by a core conductor model. In the apical parts of the cochlea complication arises due to the close packing of turns and possible alternative paths of cross-conduction between turns. Since in our experiments data were collected in the basal turn we only need to consider conditions there.

Von Békésy thoroughly investigated the spread of signals along the basal part of the cochlear partition over a length of 9 mm beginning at a distance of 0.5 mm from the basal end of the membrane. He used a set of paired electrodes placed oppositely in scala tympani and scala vestibuli along the first turn. A test signal was injected across the partition at one pair of electrodes and the resulting attenuated signal was measured at the other sensing electrode pairs. The signal attenuation he obtained amounted to 6 db per mm. Moreover, he observed that there was no 'remarkable change in the attenuation along the partition whether measured in the apical or basal direction. Thus the signal attenuation for a generator pair of electrodes situated at a position x along the partition is symmetrical with respect to x. Von Békésy employed signals with frequencies ranging from 100 Hz to 2 kHz and he could not find any dependence of the attenuation value on signal frequency. This indicates that the signal attenuation along the partition is predominantly due to the resistive properties of tissues and fluids and that the capacitive properties of the structures have negligible influence. Tasaki & Fernández applied a d.c. signal across the partition in the basal turn and they also measured a decay of signal from the site of application of 6 db per mm. Von Békésy's extensive study well established the core conductor type of the electrical attenuation along the partition and we can formulate mathematically the attenuation or weighting function.

$$W(x) = e^{-|x|/\theta} \tag{6}$$

x and θ in mm. θ denotes the length constant or decay constant of the longitudinal signal attenuation. In the core conductor model θ takes the form.

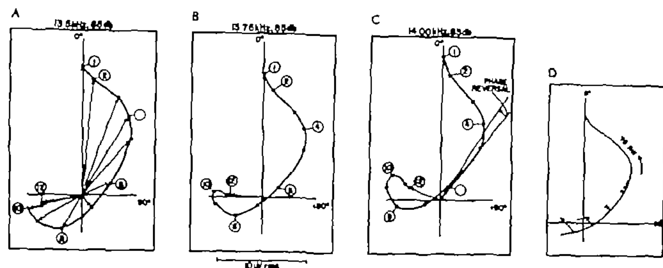

Fig 3.2 (A–C) Records (13.5 kHz, 13.75 kHz, 14 kHz) *from Fig. 3.1.A redrawn in vector form.* In (A) all output vectors are shown, in (B) and (C) all vectors apart from *1* and *12 are omitted for clarity* The trajectory connects all vector endpoints. Phase lag is counted in the clockwise direction The trajectory approaches with increasing frequency the origin of the vector plane note the concomitant increase in phase difference between *6* and *7* In (C) phase reversal occurs, *6* leading *5* in phase. In (A) and (B) the trajectory encircles the origin, in (C) it does not.

(D) Artificially induced phase reversal by addition of small vector with large phase lag and amplitude which declines as *the round window (RW) end of the* array is approached.

phase lag (13.75 kHz) into one with phase reversal (14 kHz) This is illustrated in the schematic drawing of Fig. 3.2.D Let us add to all electrode outputs in a pattern like the one at 13.75 kHz a small vector with a large phase lag and a length which declines as the basal end of the array is approached. The resulting trajectory has an appearance like the one at 14 kHz, i e it does not encircle the origin Something analogous to this vector addition may be expected to happen in reality As the stimulus frequency is increased from 13.75 to 14 kHz the wavelengths in the excitation pattern will shorten and a small group of distant *hair-cells will be operating* with slightly larger phase lag than before The influence of these distant hair-cell outputs is of course felt with an amplitude which declines towards the basal *end of the array The model provides a quali*tative explanation for the observed phase reversal and it suggests the far reaching influence of alterations in the outputs of sub*sets of hair-cell operators on the appearance* of the whole CM pattern, an influence postulated by the spatial filter hypothesis.

A further point which deserves to be mentioned concerns the situation where the trajec*tory actually crosses the origin. This situation* was thoroughly explored in a preparation where one electrode of the array recorded very nearly zero amplitude in the frequency region of the phase reversal. Thus this electrode output when plotted on the trajectory very nearly coincided with the origin of the vector plane. The output of this electrode was displayed on the oscilloscope screen and a *faint sinusoidal* signal was just noticeable in the background noise It was interesting to observe that the output signal was extremely unstable, shifting abruptly back and forth by about 180° on the oscilloscope screen All other electrode outputs, however were perfectly stable This finding, although it may seem strange at first glance can be interpreted quite plausibly Consideration of Fig 3.2 shows that the phase difference between the adjacent electrodes 6 and 7 grows continuously when the trajectory approaches the origin. *When the trajectory cros*ses the origin this phase difference becomes approximately 180° Thus a point in the immediate vicinity of the origin intermediate to *6 and 7* is framed by two vector bundles ap-

cochlea. We have to adapt this pattern to high frequencies in order to make the distribution CM(x) resulting from the spatial filter operation comparable to our high frequency records. We achieved this adaption by compressing the 'von Békésy' pattern into a shorter length of membrane. With the further assumption that hair-cell output is directly proportional to the local mechanical stimulus we obtained a hypothetical hair-cell distribution $H(x)$.

With the functions $H(x)$ and $W(x)$ (see equation (6)) given we can execute the spatial filter operation. The convolution integral

$$CM(x_0) = \int_{-\infty}^{\infty} H(x)\exp(-0.69|x_0 - x|)\,dx$$

was solved by graphical integration.

Thus the above formula, continuous in x was substituted by

$$CM(x_0) = \frac{m-n}{s}\sum_{i=0}^{s} H(x_i)\exp(-0.69|x_0 - x_i|) \quad (8)$$

where

$$x_i = n + i\,\frac{m-n}{s} \qquad i = 0, 1, \ldots, s$$

and

$$x_i, x_0 \in [n, m]$$

In equation (8) the limits of the integration interval $[-\infty, \infty]$ are replaced by the finite boundaries n, m. This is permissible provided the bulk of the pattern $H(x)$ lies within the interval $[n, m]$. For the graphical integration the interval $[n, m]$ was subdivided in $s = 10$ equal intervals.

Each $H(x_i)$ in equation (8) is characterized by an amplitude and a phase value and can therefore be represented as a vector. Thus for each x_0 ($x_0 \in [n, m]$) $CM(x_0)$ forms the vector sum of the contributions $H(x_i)$ weighted by the appropriate attenuation factor. In Fig. 3.3 all functions involved in spatial filtering are shown. The graphical integration yields the pattern $CM(x_0)$ in vector form and it can be seen in the vector plot in (A) how the weighted vectors $H(x_i)$ add up to $CM(x_0)$ for $x_0 = n$ (see

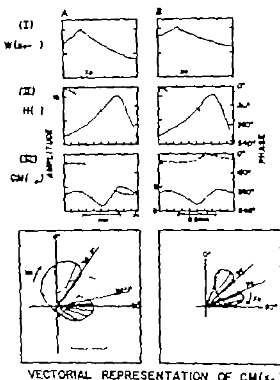

Fig. 3.3. Spatial Filtering of 'von Békésy' pattern $H(x)$. In (A) $H(\ )$ is compressed into interval $[n, m] = 2$ mm. In (B), analogous to increase in frequency $[n, m] = 1$ mm. All functions involved in spatial filtering are shown.

I. $W(x)$: weighting function, drawn for an arbitrary x_0. $W(x) = \exp(-0.69|x_0 - x|)$

II. $H(x)$: hypothetical hair-cell output distribution of the 'von Békésy type'

III. $CM(x_0)$: hypothetical CM distribution resulting from spatial filtering.

Bottom graph is the vector representation of $CM(x_0)$. The convolution integral was solved by graphical integration; $[n, m]$ was subdivided into $s = 10$ equal intervals:

$$CM(x_0) = \frac{m-n}{s}\sum_{i=0}^{s} H(x_i)\exp(-0.69|x_0 - x_i|);\ x_i, x_0 \in [n, m]$$

As an example it is shown in the vector plane in (A) how $CM(x_0)$ forms the vector sum of the weighted contributions $H(x_i)$ for $x_0 = n$ ( ). In the 'lower frequency' example (A) the trajectory encircles the origin of the vector plane, in the 'higher frequency' example (B) it does not. Note co-occurrence of amplitude minimum and large phase gradient in (A,III). ——, amplitude; – – –, phase.

3 11115

$$\theta = \frac{1}{\sqrt{dR\,dG}} \qquad (7)$$

where dR signifies the longitudinal resistance per unit length of the fluid filled canals and dG signifies the longitudinal conductance per unit length of the cochlear partition. Tasaki et al. measured the resistances involved and calculated (see equation (7) and (6)) the attenuation along the partition They obtained a value of 6 db per mm They measured an electrical impedance across the cochlear partition of 100 to 200 Ω per cm in the basal turn at a frequency of 500 Hz. At 6 kHz they found an impedance about 15% less. Since this variation in impedance with frequency is very small compared to the variation of impedance at a single frequency (500 Hz) we may consider the attenuation independent of frequency This implies, of course, that λ in equation (6) is considered a real quantity that is neglecting capacitive effects of intracochlear structures.

Data considered so far concerned the attenuation of signals across the cochlear partition. The result unanimously achieved, gives an attenuation of 6 db per mm, i.e a decay constant $\theta = 1.45$ mm ($\lambda = 0.69$) However it needs to be clarified whether this value of θ is a good approximation to the real situation where the signal is generated by the hair cells within the organ of Corti, presumably across the reticular lamina and not as in the above test cases across the cochlear partition It is likely that a pair of electrodes, the one electrode situated in scala media and the other in scala tympani, mimics the real situation better than does a pair of electrodes situated across the whole cochlear partition Experiments to explore the attenuation along the basilar membrane have been done with electrodes inserted into scala media and scala tympani

Misrahy et al measured the resistances involved in this latter situation and they calculated (using equation (7)) for the basal turn a decay constant $\theta = 1.18$ mm for the signal spread along the basilar membrane However Johnstone et al., measuring the spread of current pulses along the membrane with electrodes in scala media, obtained an average length constant $\theta = 2$ mm in the first turn The discrepancy between these results is probably due to the fact that these experiments are extremely difficult to execute requiring utmost surgical cleanliness a requirement not easy to meet when handling sets of recording electrodes. Taking the arithmetic mean of the two values gives a mean length constant $\theta = 1.59$ mm a value not significantly different from the length constant along the whole cochlear partition Thus for the mathematical operations in this thesis we used von Békésy's value for the length constant corresponding to a signal decay of 6 db per mm

The weighting function in equation (6) takes into account the longitudinal spread of signal along the cochlear scalae it does not take account of the signal variation across the scalae. In accordance with the core conductor model we may neglect as a first approximation the effect of the distance between electrode tips and the basilar membrane on the CM distribution In Fig 2 11 A the CM pattern for the same stimulus parameter is shown measured at two different depths of insertion of the electrode array into scala tympani thus the distance between electrode tips and the basilar membrane was slightly different in the two records. There are only minor differences between the two patterns and we may therefore regard the potential variation across the scala tympani negligible as a first approximation

Spatial filtering of hypothetical patterns $H(x)$

It is expedient to begin the mathematical analysis of the spatial filter effect by subjecting a function $H(x)$ to spatial filtering which has the shape of the mechanical excitation curves measured by von Békésy The highest stimulus frequency at which von Békésy observed the complete mechanical excitation pattern along the membrane was 300 Hz the pattern extended from about 19 mm to 29 mm along the basilar membrane of the human

cochlea. We have to adapt this pattern to high frequencies in order to make the distribution CM(x) resulting from the spatial filter operation comparable to our high frequency records. We achieved this adaption by compressing the 'von Békésy' pattern into a shorter length of membrane. With the further assumption that hair-cell output is directly proportional to the local mechanical stimulus we obtained a hypothetical hair-cell distribution $H(x)$.

With the functions $H(x)$ and $W(x)$ (see equation (6)) given we can execute the spatial filter operation. The convolution integral

$$CM(x_0) = \int_{-\infty}^{\infty} H(x) \exp(-0.69|x_0 - x|)\, dx$$

was solved by graphical integration.

Thus the above formula, continuous in x was substituted by

$$CM(x_0) = \frac{m-n}{s} \sum H(x_i) \exp(-0.69|x_0 - x_i|) \quad (8)$$

where

$$x_i = \quad + i\frac{m}{s} \frac{n}{} \quad i = 0\ 1 \quad s$$

and

$x \ \ x_0 \in [n, m]$

In equation (8) the limits of the integration interval $[-\infty\ \ \infty]$ are replaced by the finite boundaries n, m. This is permissible provided the bulk of the pattern $H(x)$ lies within the interval $[n\ m]$. For the graphical integration the interval $[n\ \ m]$ was subdivided in $s = 10$ equal intervals.

Each $H(x_i)$ in equation (8) is characterized by an amplitude and a phase value and can therefore be represented as a vector. Thus for each x_0 ($x_0 \in [n\ m]$) CM(x_0) forms the vector sum of the contributions $H(x_i)$ weighted by the appropriate attenuation factor. In Fig. 3.3 all functions involved in spatial filtering are shown. The graphical integration yields the

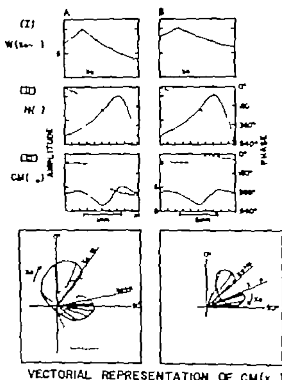

Fig. 3.3. Spatial Filtering of von Békésy pattern $H(\ )$. In (A) $H(x)$ is compressed into interval $[n, m] = 2$ mm. In (B), analogous to increase in frequency $[n, m] = 1$ mm. All functions involved in spatial filtering are shown.

I. $W(x)$: weighting function, drawn for an arbitrary x_0, $W(x) = \exp(-0.69|x_0 - x|)$.

II. $H(x)$: hypothetical hair-cell output distribution of the von Békésy type.

III. CM(x_0): hypothetical CM distribution resulting from spatial filtering.

Bottom graph is the vector representation of CM(x_0). The convolution integral was solved by graphical integration; $[n, m]$ was subdivided into $s = 10$ equal intervals.

$$CM(x_0) \quad \frac{m-n}{s} \sum_{i=0} H(x_i) \exp(-0.69|x_0 - x_i|); \quad x_0 \in [n, m]$$

As an example it is shown in the vector plane in (A) how CM(x_0) forms the vector sum of the weighted contributions $H(x_i)$ for x_0 = n ( ). In the 'lower frequency' example (A) the trajectory encircles the origin of the vector plane, in the 'higher frequency' example (B) it does not. Note co-occurrence of amplitude minimum and large phase gradient in (A,III). —— amplitude - - - - phase.

pattern CM(x_0) in vector form and it can be seen in the vector plot in (A) how the weighted vectors $H(x_i)$ add up to CM(x_0) for $x_0 = n$ (see

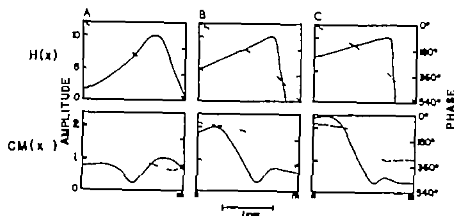

Fig 3.4 Modification of von Békésy type pattern $H(x)$. (A) $H(x)$ redrawn from Fig. 3.3 A. (B, C) Flattening the basal slope and steepening the apical slope of the envelope of $H(x)$ produces theoretical curves $CM(x)$ more similar to experimental CM patterns. —— amplitude - - - phase.

dashed line in vector diagram (A)) By plotting the amplitude and phase pattern of $CM(x_0)$ separately we obtain the hypothetical cochlear microphonic distribution $CM(x_0)$ in a fashion ready for comparison with experimental patterns.

In Fig. 3 3 A $H(x)$ was compressed into an interval length of 2 mm while in (B) analogous to an increase in frequency the interval length was only 1 mm Let us call A the 'lower frequency' and B the 'higher frequency' example

Practically all significant features of the resulting patterns $CM(x_0)$ are consistent with experimental findings. The amplitude of $CM(x_0)$ in the 'higher frequency' case is smaller than in the 'lower frequency' case this is compatible with real patterns which showed an overall drop in amplitude with increasing stimulus frequency The overall phase variation along the space coordinate in the 'higher frequency' example is very small a feature well shown by the experimental patterns in Fig 3 1 A at high stimulus frequencies. In the 'low frequency' example there is progressive phase lag along x_0 thus the trajectory in the vector representation encircles the origin of the vector plane In the high frequency example no encirclement of the origin occurs and the phase pattern shows phase reversal the more apical part of the pattern leading in phase the more basal part The occurrence of phase reversal with increase in stimulus frequency was one of the main characteristics of experimental CM patterns. In the 'lower frequency' example we observe the co-occurrence of an amplitude minimum and a large phase gradient. This also was a main characteristic of experimental CM patterns.

Thus it is demonstrated that all salient features of the measured CM patterns can be qualitatively reproduced by spatially filtering an excitation pattern of the von Békésy type It should be noted that $CM(x_0)$ at a particular point x_0 does not reflect the hair-cell output at this point x_0 this can be clearly seen in Fig. 3.3 Thus the notion held by several investigators that an electrode records local hair-cell activity is proved incorrect

Quantitative comparison between theoretical and experimental CM patterns

In the foregoing section we showed the excellent qualitative agreement between theoretical CM patterns deducible from the 'von Békésy type' function $H(x)$ and our own experimental data. Yet, closer inspection of the theoretical curves $CM(x_0)$ in Fig 3 3 reveals that the quantitative agreement with measured patterns is rather poor this applies especially to the shape of the amplitude pattern of $CM(x_0)$ which shows a large distant maximum.

We attempted to improve the quantitative fit between the theoretical and measured CM patterns by systematically modifying the shape of the hypothetical pattern $H(x)$. Since $H(x)$ consists of two parameter distributions, those of amplitude and phase, we can manipulate either or both of the two functions. Due to the lack

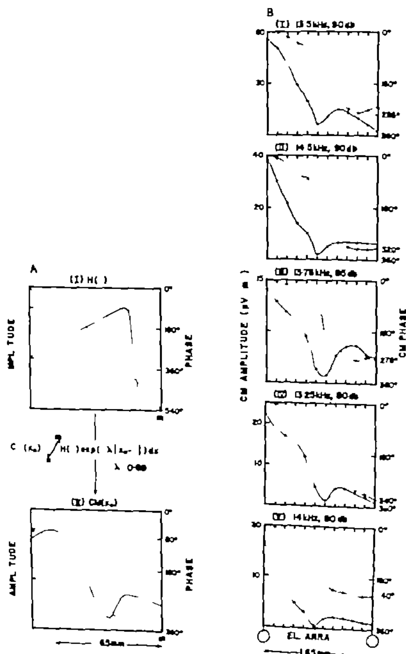

Fig 3.5 (A.I, II). Hypothetical $H(x)$ and $CM(x_0)$ re drawn from Fig. 3.4 B. Compare $CM(x_0)$ over the length 1.65 mm with experimental CM patterns in (B I–V)

(B I–V) Experimental CM amplitude and phase patterns obtained from five different guinea pigs. Stimulus parameters are essentially the same (stimulus frequency varied from 13.5 kHz to 14.5 kHz; SPL varied from 80 to 90 db) Note: Distinct amplitude minimum around 6 and 7, flat amplitude maximum around 8 and 9, large phase gradient in the region of amplitude minimum. On account of good quantitative agreement between $CM(x_0)$ (A.II) and experimental CM patterns (B.I–V) assume $H(x)$ in (A.I) to be a close approximation— $H(x)^*$—to the real hair cell output patterns for the stimuli in (B.I–V), i.e. for stimulus frequencies between 13.5 and 14.5 kHz. —— amplitude, - - - phase.

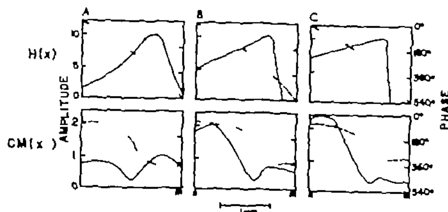

Fig 3.4 Modification of 'von Békésy type' pattern $H(x)$. (A) $H(x)$ redrawn from Fig. 3.3.A. (B, C) *Flattening the basal slope and steepening the apical slope of the envelope of $H(x)$ produces* theoretical curves $CM(x_0)$ more similar to experimental CM patterns. —— amplitude ---- phase.

dashed line in vector diagram (A)) By plotting the amplitude and phase pattern of $CM(x_0)$ separately we obtain the hypothetical cochlear microphonic distribution $CM(x_0)$ in a fashion ready for comparison with experimental patterns.

In Fig 3 3.A $H(x)$ was compressed into an interval length of 2 mm while in (B) analogous to an increase in frequency the interval length was only 1 mm. Let us call A the 'lower frequency' and B the higher frequency' example.

Practically all significant features of the resulting patterns $CM(x_0)$ are consistent with experimental findings. The amplitude of $CM(x_0)$ in the higher frequency case is smaller than in the lower frequency' case this is compatible with real patterns which showed an over all drop in amplitude with increasing stimulus frequency The overall phase variation along the space coordinate in the higher frequency' example is very small a feature well shown by the experimental patterns in Fig 3 1 A at high stimulus frequencies. In the low frequency' example there is progressive phase lag along x_0, thus the trajectory in the vector representation encircles the origin of the vector plane In the high frequency' example no encirclement of the origin occurs and the phase pattern shows phase reversal, the more apical part of the pattern leading in phase the more basal part The occurrence of phase reversal with increase in stimulus frequency was one of the main characteristics of experimental CM patterns. In the 'lower frequency example we observe the co-occurrence of an amplitude minimum and a large phase gradient. This also was a main characteristic of experimental CM patterns.

Thus it is demonstrated that all salient features of the measured CM patterns can be qualitatively reproduced by spatially filtering an excitation pattern of the 'von Békésy type It should be noted that $CM(x_0)$ at a particular point x_0 does not reflect the hair-cell output at this point x_0 this can be clearly seen in Fig. 3 3 Thus the notion held by several investigators that an electrode records local hair-cell activity is proved incorrect.

Quantitative comparison between theoretical and experimental CM patterns

In the foregoing section we showed the excellent qualitative agreement between theoretical CM patterns deducible from the 'von Békésy type function $H(x)$ and our own experimental data. Yet, closer inspection of the theoretical curves $CM(x_0)$ in Fig 3.3 reveal that the quantitative agreement with measured patterns is rather poor this applies especially to the shape of the amplitude pattern of $CM(x_0)$ which shows a large distant maximum

We attempted to improve the quantitative fit between the theoretical and measured CM patterns by systematically modifying the shape of the hypothetical pattern $H(x)$ Since $H(x)$ consists of two parameter distributions those of amplitude and phase we can manipulate either or both of the two functions. Due to the lack

H(x) and the frequency response curve

We obtained from the considerations outlined in the previous section a distribution $H(x)^*$ representing the approximate shape of the hair cell activity pattern along the membrane at stimulus frequencies from 13.5 kHz to 14.5 kHz. We are now in the position to compare this information about the excitation pattern with the data available from mechanical measurements. However $^*H(x)$ is a distribution along the space variable x while all the mechanical data are frequency response curves of points along the membrane, i.e. they are functions of the frequency variable. For the comparison between the two sets of data we have to deduce from the shape of $H(x)$ the corresponding frequency response curve. This deduction can be done provided we know the conversion formula relating the space variable x to the stimulus frequency f in the guinea pig's cochlea.

Greenwood (1961) formulated the connection between stimulus frequency and the location of the maximum displacement along the basilar membrane in the guinea pig. He used the expression.

$$f = A(10^{ar} - 1) \qquad (9\,a)$$

where f denotes stimulus frequency in Hz and r denotes the distance in mm of the maximum displacement from the apical end of the membrane. In this thesis we measured the spatial coordinate x from the basal end of the membrane. In the guinea pig the basilar membrane has a total length of 18.5 mm. Thus by using the substitution

$$r = 18.5 - x$$

we can write equation (9 *a*) in the form.

$$f = A(10^{a(18.5-x)} - 1) \qquad (9\,b)$$

Greenwood determined the values (A, a) by fitting the function (9 *a*) to von Békésy's mechanical data measured in the upper turns of the cochlea. He obtained two sets of values, the one set giving rise to function G

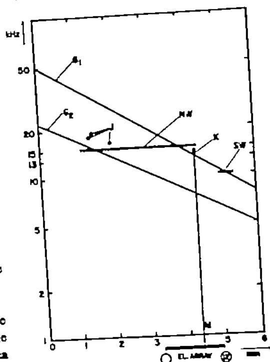

Fig. 3.7 Stimulus frequency on logarithmic scale plotted versus locus of maximum displacement along the guinea pig's basilar membrane. The space coordinate is measured from the basal end of the membrane; it is given in mm.

G_1 and G: Greenwood's functions.

SW: Damage of organ of Corti after overstimulation with 10 kHz tone, observed by Smith & Wever (1949).

NW: Region of swollen hair-cell nuclei after exposure to 15 kHz tone, observed by Neubert & Wustenfeld (1955).

$\vdash$: Frequency of maximum displacement for points along the guinea pig membrane, observed by Johnstone & Boyle (1967) and Johnstone (1969).

K: The position of the electrode array relative to the space coordinate is shown. M indicates the position of the envelope maximum of $H(x)^*$ according to Fig. 3.5. M falls into the region between electrodes 8 and 9. With M and the stimulus frequencies (13.5 kHz to 14.5 kHz) given for which $H(x)^*$ is considered an approximation to the hair-cell output distribution we can plot our results into the graph. They are marked K and they show good agreement with G.

$$G: \; f = 166.2(10^{[illegible](18.5-x)} - 1)$$

the other set leading to G_2.

$$G_2: \; f = 253(10^{[illegible](18.5-x)} - 1)$$

Both functions G and G_2 are shown in Fig. 3.7. The function G_2 fits the low frequency

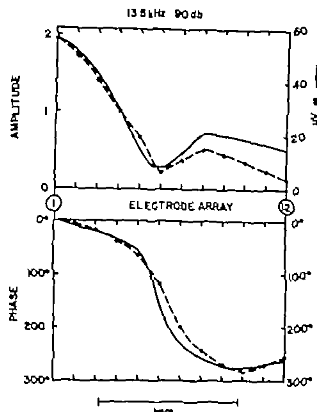

Fig. 3.6. Hypothetical CM(x_0) from Fig. 3.4 B and Fig. 3.5.A.II drawn together with experimental CM pattern from Fig. 3.5 B I. The relative amplitude for CM(x_0) is indicated on the left hand scale, the amplitude for the experimental 13.5 kHz, 90 db pattern is indicated on the right hand scale in μV rms. Both, amplitude and phase patterns show good quantitative agreement. —— hypothetical CM(x_0) – – – measured CM pattern at 13.5 kHz, 90 db.

of experimental data on the longitudinal phase variation in the mechanical excitation pattern at frequencies beyond 300 Hz we left the phase pattern of $H(x)$ unchanged. The amplitude envelope of $H(x)$ was modified and the corresponding CM(x_0) was calculated by graphical integration according to equation (8).

In Fig. 3.4 the result of this procedure is shown. Fig. 3.4 A displays the 'von Békésy type' pattern $H(x)$ used in Fig. 3.3 A. It can be seen that flattening the basal slope and steepening the apical slope of the envelope of $H(x)$ produces CM(x_0) patterns which approximate in shape very closely to experimental CM patterns. The CM(x) in Fig. 3.4 B gives the closest fit and it is redrawn in Fig. 3.5 A together with experimental CM distributions.

It can be seen at once that there is very good agreement between the hypothetical CM(x_0) in Fig. 3.5 A.II and the measured CM patterns in Fig. 3.5 B I to V. The experimental patterns were obtained from five different guinea pigs. The stimulus parameters in all five cases were essentially the same, thus the stimulus frequency varied only from 13.5 kHz to 14.5 kHz, and the stimulus intensity varied from 80 to 90 db SPL. All experimental amplitude patterns exhibit a distinct minimum around electrodes 6 and 7 and a flat maximum around electrodes 8 and 9. In the region of the amplitude minimum all patterns show the characteristic large phase variation. The overall phase change along the array amounts in the five cases to 285, 320, 276, 350, 240 respectively. For the comparison between the theoretical and experimental CM patterns, we consider the theoretical pattern over a length of 1.65 mm equal to the width of the electrode array. The overall phase variation in this length interval of the theoretical curve has a value of 280. Undoubtedly there is very good quantitative agreement between the theoretical and experimental curves.

In order to show the quantitative fit more clearly the measured CM pattern of Fig. 3.5 B.I was redrawn along with the theoretical pattern of Fig. 3.5 A II in the same diagram in Fig. 3.6. The excellent agreement between the hypothetical and the measured CM patterns, well documented in Fig. 3.6, suggests the following logical conclusion: the hypothetical pattern $H(x)$ from which the hypothetical CM(x_0) in Fig. 3.6 was deduced must approximate very closely to the real hair-cell output pattern which produced the measured CM distribution in Fig. 3.6.

Thus in the following discussion we shall assume that the hair-cell output pattern at stimulus frequencies from 13.5 kHz to 14.5 kHz can be represented by the hypothetical pattern "$H(x)$" given in Fig. 3.5 A I. (Writing $H(x)$ with inverted commas indicates that "$H(x)$" is considered to be an approximation to the real curve.)

shape with increasing frequency and the wave lengths become shorter Thus the excitation pattern is not simply translated towards the basal end. However over a very narrow frequency range we may use the shift in the CM pattern as a first approximation.

We may conclude from the above discussion that G_1 describes adequately the relationship between stimulus frequency and the locus of maximum excitation in the basal part of the guinea pig's cochlea. By expressing x in terms of f we obtain G_1 in the form:

$$G \quad x = 18.5 - \frac{1}{0\ 134} \log\left(\frac{f}{166.2} + 1\right)$$

at high stimulus frequencies

$$\frac{f}{166.2} \gg 1$$

thus

$$x \approx 18.5 - \frac{1}{0\ 134} \log \frac{f}{166.2} \qquad (9\,c)$$

According to equation (9 c) there exists a linear relationship between x and the logarithm of stimulus frequency An octave change in frequency corresponds to a spatial shift Δx of the location of the maximum excitation given by (9 c):

$$\Delta x = \frac{1}{0\ 134} \log 2 = 2.25$$

Thus the maximum shifts by 2.25 mm per octave This is the information needed for the deduction of the frequency response curve from $H(x)$ It enables us to express the slopes of the response curve in db per octave.

Fig. 3 9 shows the envelope of the pattern $H(x)$ corresponding to the experimental CM pattern measured at 13.5 kHz, 90 db. ("$H(x)$ in Fig. 3 9 is the same pattern shown in Fig. 3 4.*B* and Fig. 3 4.*A* I) Let us consider the frequency response curve of the point $M(13.5)$ at which $H(x)$ has its maximum. Increase in stimulus frequency causes a basal shift of the

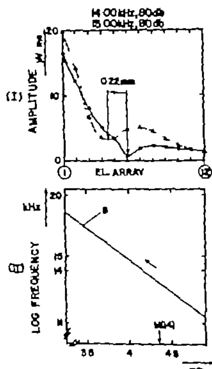

Fig 3.8 The shift in the CM amplitude minimum is taken as measure for the shift in the envelope maximum of the corresponding $H(x)$

I. For an increase in stimulus frequency from 14 to 15 kHz the CM amplitude minimum shifts by approximately 0.22 mm. ●—● CM amplitude pattern at 14 kHz, 80 db ▲—▲ CM amplitude pattern at 15 kHz, 80 db.

II. Stimulus frequency on log. scale versus locus of maximum displacement. G is plotted over the space interval given by the width of the electrode array $M(14)$ denotes the position of the envelope maximum of $H(x)$" at 14 kHz according to K in Fig. 3 7 The spatial shift of 0.22 mm defines the 15 kHz point in the graph. The shift tendency follows G 14 kHz point; ▲ 15 kHz point inferred from the shift in CM amplitude minimum.

pattern $H(x)$" and the output at $M(13.5)$ drops according to the apical slope of $H(x)$ Similarly with decrease in stimulus frequency the output at $M(13.5)$ falls according to the basal slope of $H(x)$" Thus the apical slope of $H(x)$ defines the high frequency branch and the basal slope of $H(x)$" defines the low frequency branch of the frequency response curve.

We can express the slopes of the envelope of $H(x)$" in db per mm. This logarithmic slope

data of von Békésy slightly better than G_1 however it does not take into account the high frequency response of the guinea pig's cochlea Greenwood established G_1 in reference to the finding of Pestalozza & Davis (1956) These investigators obtained electrical responses from the guinea pig s cochlea for stimulus frequencies up to 50 kHz. More recently Wever et al (1963) confirmed 50 kHz as the upper frequency limit of the guinea pig s hearing range by electrical recordings from the cochlea. Thus it appears that G_1 is the more likely function at least as far as the basal part of the cochlea is concerned

There is some more evidence in favour of G_1 Davis and associates (1953) determined histologically the injury of cochlear structures after exposing the guinea pig s ear to intense tones. The injury due to an 8 kHz tone was located in the upper third of the first turn G_1 is compatible with this result Smith & Wever (1949) registered an injury of the organ of Corti centered at 5 mm from the basal end of the membrane after excessive exposure to a 10 kHz tone It can be seen from Fig 3 7 that this result marked SW agrees with G_1 Neubert & Wüstenfeld (1955) explored the extension of the excitation pattern along the basilar membrane by observing the swelling of hair cell nuclei after exposing the guinea pig's ear to prolonged tonal stimuli For a stimulus of 15 kHz and 60 db SPL, lasting for 120 minutes, they reported swelling of nuclei over a well defined region in the basal turn Their result is plotted in Fig. 3 7 marked NW It can be seen that NW overlaps with both functions G_1 and G_2 On the basis of the asymmetric shape of the excitation pattern which has a flat basal and a steep apical slope one would expect that the maximum displacement in the case NW would rather fall on G_1 than on G_2 Thus the evidence mentioned so far fully supports G_1 as the function relating stimulus frequency and locus of maximum displacement in the basal turn

Johnstone & Boyle (1967) and Johnstone (1969) measured with the Mössbauer technique the frequency of maximum response at three points along the basal part of the guinea pig s membrane Their results are shown in Fig 3 1 marked J The results neither fall exactly on G_2 nor on G_1 In the region of the membrane where the results were obtained one would predict from G_1 a frequency of maximum response around 30 kHz. The measured values, however give best frequencies around 20 kHz. It is tempting to speculate that this lowering in the maximum response frequency could be due to the presence of the Mössbauer probe. It is not unlikely that the probe loads the membrane increasing the mass of the system locally Such an increase in the inertia component of the system would inevitably reduce the frequency of maximum response to lower values.

It is interesting to consider the position of the maximum amplitude in "$H(x)$" in relation to G_1 It follows from the fitting procedure outlined in the previous section that the maximum in $H(x)$" occurs between electrodes 8 and 9 (see also Fig 3.9) In Fig 3 7 the location of the maximum is marked M The stimulus frequency (13.5 kHz to 14.5 kHz) and M define our results in Fig 3 7 (marked K) It can be seen that our results agree very well with G_1

There is a further property of our data which agrees with G_1 Fig. 3 8 I shows a shift (0 22 mm) of the minimum in the CM amplitude pattern in the basal direction for an increase in stimulus frequency from 14 to 15 kHz. Let us take this shift in the CM pattern as a direct measure of the shift of the envelope in the corresponding "$H(x)$" In Fig 3 8.II the location of the maximum M(14) for the 14 kHz pattern $H(x)$" is plotted according to Fig 3 7 The 15 kHz point in Fig. 3 8 II was obtained with the above shift of 0.22 mm in the basal direction It is obvious that the tendency of the basal shift follows G very closely Of course the shift in the minimum of the CM pattern is a very rough measure of the shift in the corresponding "$H(x)$" because the excitation pattern along the membrane changes

pe with increasing frequency and the wave gths become shorter Thus the excitation tern is not simply translated towards the al end. However over a very narrow fre ency range we may use the shift in the CM ttern as a first approximation.

We may conclude from the above discussion at G_1 describes adequately the relationship etween stimulus frequency and the locus of aximum excitation in the basal part of the uinea pig's cochlea. By expressing x in terms of f we obtain G_1 in the form.

$$G\quad x = 18.5 - \frac{1}{0.134}\log\left(\frac{f}{166.2}+1\right)$$

at high stimulus frequencies

$$\frac{f}{166.2} > 1$$

thus

$$x \approx 18.5 \quad \frac{1}{0.134}\log\frac{f}{166.2} \qquad (9c)$$

According to equation (9 c) there exists a linear relationship between x and the logarithm of stimulus frequency An octave change in frequency corresponds to a spatial shift Δx of the location of the maximum excitation given by (9 c)

$$\Delta x = \frac{1}{0.134}\log 2 \quad 2.25$$

Thus the maximum shifts by 2.25 mm per octave This is the information needed for the deduction of the frequency response curve from $H(x)$ It enables us to express the slopes of the response curve in db per octave.

Fig 3.9 shows the envelope of the pattern $H(x)$ corresponding to the experimental CM pattern measured at 13.5 kHz, 90 db. ("$H(x)$" in Fig. 3.9 is the same pattern shown in Fig. 3.4.*B* and Fig 3.4.*A* 1). Let us consider the frequency response curve of the point *M*(13.5) at which $H(x)$ has its maximum. Increase in stimulus frequency causes a basal shift of the pattern $H(x)$ and the output at *M*(13.5) drops according to the apical slope of "$H(x)$". Similarly with decrease in stimulus frequency the output at *M*(13.5) falls according to the basal slope of $H(x)$" Thus the apical slope of $H(x)$ defines the high frequency branch and the basal slope of $H(x)$" defines the low frequency branch of the frequency response curve.

We can express the slopes of the envelope of $H(x)$" in db per mm. This logarithmic slop

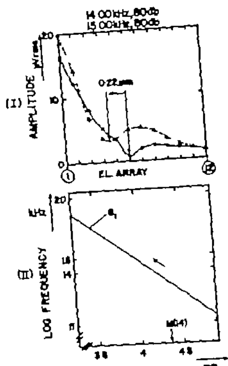

Fig 3.8 The shift in the CM amplitude minimum is taken as a measure for the shift in the envelope maximum of the corresponding $H(x)$"

I. For an increase in stimulus frequency from 14 to 15 kHz the CM amplitude minimum shifts by approximately 0.22 mm. ●—● CM amplitude pattern at 14 kHz, 80 db; ▲—▲ CM amplitude pattern at 15 kHz, 80 db.

II. Stimulus frequency on log. scale versus locus of maximum displacement. G_1 is plotted over the space interval given by the width of the electrode array *M*(14) denotes the position of the envelope maximum of $H(x)$" at 14 kHz according to *K* in Fig. 3.7 The spatial shift of 0.22 mm defines the 15 kHz point in the graph. The shift tendency follows G ● 14 kHz point; ▲ 15 kHz point inferred from the shift in CM amplitude minimum.

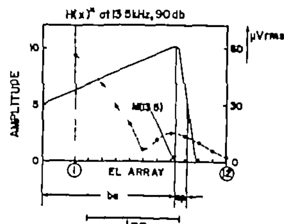

Fig. 3.9. Amplitude envelope of $H(x)$ redrawn from Fig. 3.4 B and Fig. 3.5.A.I. The relative amplitude of $H(x)$ is indicated on the left hand scale. In order to emphasize the deductive source of $H(x)$ we have plotted the experimental CM amplitude pattern obtained at 13.5 kHz, 90 db for comparison (CM pattern replotted from Fig. 3.5 B.I. and Fig. 3.6.). The CM amplitude is given in μV rms on the right hand scale. Thus $H(x)$ is considered a close approximation to the shape of the real hair-cell output distribution which produced the experimental CM pattern. The position of the envelope maximum of $H(x)$ is marked $M(13.5)$. In $H(x)$ the amplitude falls by 6 db over a distance $ba = 1.45$ mm in the basal and a distance $ap = 0.124$ mm in the apical direction. —— envelope of $H(x)$ --- experimental CM amplitude pattern at 13.5 kHz, 90 db.

measure is strictly speaking not absolutely correct because it requires an exponential shape of the envelope. We used a *triangular* shape of envelope in the fitting procedure for convenience. However the logarithmic measure is sufficiently accurate for our purposes. The amplitude in "$H(x)$" drops by 6 db in the basal direction over a distance $ba = 1.45$ mm and in the apical direction over a distance $ap = 0.124$ mm. Thus we obtain as numerical values for the slopes in "$H(x)$"

$$\text{basal slope: } \frac{6}{1.45}\frac{\text{db}}{\text{mm}}$$

$$\text{apical slope: } \frac{6}{0.124}\frac{\text{db}}{\text{mm}}$$

An octave change in stimulus frequency causes a shift of "$H(x)$" by 2.25 mm. It follows for the high and low frequency slope of the response curve of $M(13.5)$

$$\text{low frequency slope: } \frac{6}{1.45} 2.25 \frac{\text{db}}{\text{mm}}\frac{\text{mm}}{\text{octave}} = 9.3\frac{\text{db}}{\text{octave}}$$

$$\text{high frequency slope: } \frac{6}{0.124} 2.25 \frac{\text{db}}{\text{mm}}\frac{\text{mm}}{\text{octave}} = 109\frac{\text{db}}{\text{octave}}$$

The slope values of the frequency response curve derived from "H(x)" are consistent with mechanical data obtained with the Mössbauer technique. This clearly indicates that "$H(x)$" must be a close approximation to the excitation pattern along the membrane.

"$H(x)$" was established by comparing a theoretical CM(x) with experimental CM patterns measured at an SPL of 80 to 90 db (see Fig. 3.5). Thus "$H(x)$" represents the hair-cell output distribution at these stimulus intensities. The question arises whether the shape of "$H(x)$" can be regarded as a close approximation to the shape of the excitation pattern at stimulus intensities less than 80 to 90 db SPL. This question can be answered by considering the shape of the CM pattern at different sound pressures, say from 35 to 85 db SPL. Provided *there is no significant change in the shape* of the CM pattern we can safely assume that the shape of the corresponding "$H(x)$" does not alter significantly with increasing sound pressure (up to 90 db SPL).

The result of such an experiment is shown in Fig. 3.10 A. The CM amplitude pattern of a 13 kHz tone is displayed for SPLs ranging from 35 to 85 db. The amplitudes are plotted on a logarithmic scale and it can be seen that all electrode outputs exhibit perfectly linear intensity functions up to about 65 db. It implies, of course, that the shape of the CM pattern and that of the corresponding "$H(x)$" does not change because all electrode outputs grow in equal proportion. This is not at all surprising since the linear dependence of CM on sound pressure up to 60 or 70 db is a well known fact. More interesting, however, is the

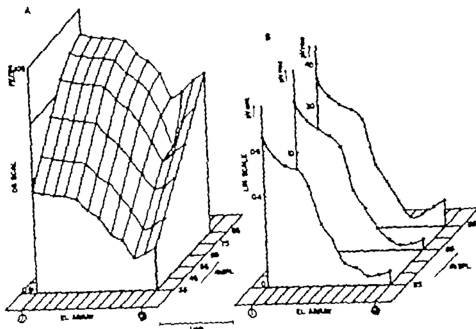

Fig. 3.10. CM amplitude pattern at 13 kHz measured for SPLs from 35 to 85 db

(A) CM amplitude plotted on logarithmic scale. The intensity functions of all electrode outputs are linear up to about 65 db. Thereafter onset of non-linearity and slight differential growth of electrode outputs.

(B) CM amplitude patterns for 35, 65 and 85 db drawn on linear scale. Output at 1 is given equal height in the patterns in order to facilitate comparison between the shape of the patterns. There is only a slight relative increase in the outputs of the apical part of the array at 85 db relative to the lower intensity patterns.

region between 65 and 85 db, the region of onset of nonlinearity. According to Fig. 3.10.A the intensity functions of the different electrodes become slightly different. At 11 and 12 linearity persists, at the remaining electrodes slight deviation from linearity is noticeable. Thus it is clear that the corresponding $H(x)$" underwent slight alteration in shape between 65 and 85 db. Nevertheless, this change in shape must have been very small indeed. In Fig. 3.10.B the 35, 65 and 85 db patterns were redrawn on a linear amplitude scale. In the drawing the output 1 is given equal height in the three patterns in order to facilitate comparison of their shapes. It is obvious that the shapes are almost identical with only a slight growth in the distant electrodes at 85 db relative to the lower intensity patterns.

We can safely assume that the shape of $H(\ )$ is a close approximation to the shape of the hair-cell output pattern for sound pressures up to 90 db SPL. The frequency response curve deduced from $H(x)$ at 90 db is therefore also valid at lower SPLs.

Inversion of the spatial filter operation

The mathematical method used so far was essentially a graphical procedure. We assumed a certain pattern $H(x)$; we calculated the corresponding theoretical $CM(x)$ and compared it with experimental curves. In the event of a good agreement between the theoretical $CM(x)$ and an experimental CM pattern we postulated $H(x)$ as a close approximation to the real hair-cell output pattern along the basilar membrane. This way of operation proved very successful and our data suggest an $H(x)$" fully compatible with the information about the mechanical behaviour of the membrane in the basal turn.

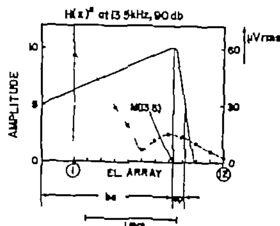

Fig 3.9 Amplitude envelope of $H(x)$ redrawn from Fig. 3 4 B and Fig. 3.5 A.I. The relative amplitude of $H(x)$ is indicated on the left hand scale. In order to emphasize the deductive source of $H(x)$ we have plotted the experimental CM amplitude pattern obtained at 13.5 kHz, 90 db for comparison (CM pattern replotted from Fig. 3.5 B.I and Fig. 3 6.) The CM amplitude is given in μV rms on the right hand scale. Thus $H(x)$ is considered a close approximation to the shape of the real hair-cell output distribution which produced the experimental CM pattern The position of the envelope maximum of $H(x)$ is marked $M(13.5)$. In $H(x)$ the amplitude falls by 6 db over a distance $ba = 1\ 45$ mm in the basal and a distance $ap = 0\ 124$ mm in the apical direction. —— envelope of $H(x)$ – – – experimental CM amplitude pattern at 13.5 kHz, 90 db.

measure is strictly speaking not absolutely correct because it requires an exponential shape of the envelope We used a triangular shape of envelope in the fitting procedure for convenience However the logarithmic measure is sufficiently accurate for our purposes. The amplitude in "$H(x)$" drops by 6 db in the basal direction over a distance $ba = 1\ 45$ mm and in the apical direction over a distance $ap = 0\ 124$ mm Thus we obtain as numerical values for the slopes in $H(x)$"

basal slope $\frac{6}{1\ 45}\frac{\text{db}}{\text{mm}}$

apical slope $\frac{6}{0\ 124}\frac{\text{db}}{\text{mm}}$

An octave change in stimulus frequency causes a shift of "$H(x)$ by 2.25 mm It follows for the high and low frequency slope of the response curve of $M(13.5)$

low frequency slope. $\frac{6}{1\ 45}\,2.25\,\frac{\text{db}}{\text{mm}}\,\frac{\text{mm}}{\text{octave}} = 9\ 3\,\frac{\text{db}}{\text{octave}}$

high frequency slope. $\frac{6}{0\ 124}\,2.25\,\frac{\text{db}}{\text{mm}}\,\frac{\text{mm}}{\text{octave}} = 109\,\frac{\text{db}}{\text{octave}}$

The slope values of the frequency response curve derived from "H(x)" are consistent with mechanical data obtained with the Mössbauer technique. This clearly indicates that "$H(x)$" must be a close approximation to the excitation pattern along the membrane

$H(x)$" was established by comparing a theoretical CM(x) with experimental CM patterns measured at an SPL of 80 to 90 db (see Fig 3 5) Thus "$H(x)$" represents the hair-cell output distribution at these stimulus intensities. The question arises whether the shape of "$H(x)$" can be regarded as a close approximation to the shape of the excitation pattern at stimulus intensities less than 80 to 90 db SPL. This question can be answered by considering the shape of the CM pattern at different sound pressures, say from 35 to 85 db SPL. Provided there is no significant change in the shape of the CM pattern we can safely assume that the shape of the corresponding "$H(x)$" does not alter significantly with increasing sound pressure (up to 90 db SPL)

The result of such an experiment is shown in Fig 3 10 A. The CM amplitude pattern of a 13 kHz tone is displayed for SPLs ranging from 35 to 85 db The amplitudes are plotted on a logarithmic scale and it can be seen that all electrode outputs exhibit perfectly linear intensity functions up to about 65 db It implies, of course that the shape of the CM pattern and that of the corresponding $H(x)$" does not change because all electrode outputs grow in equal proportion This is not at all surprising since the linear dependence of CM on sound pressure up to 60 or 70 db is a well known fact. More interesting, however is the

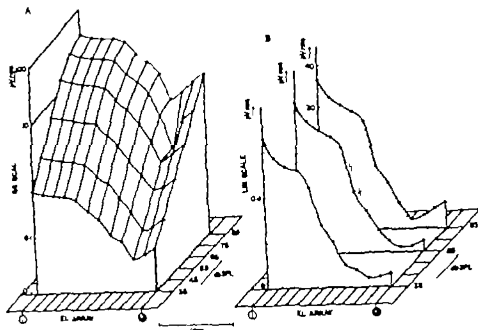

Fig. 3.10. CM amplitude pattern at 13 kHz measured for SPLs from 35 to 85 db.

(A) CM amplitude plotted on logarithmic scale. The intensity functions of all electrode outputs are linear up to about 65 db. Thereafter onset of nonlinearity and slight differential growth of electrode outputs.

(B) CM amplitude patterns for 35, 65 and 85 db drawn on linear scale. Output at 1 is given equal height in the patterns in order to facilitate comparison between the shape of the patterns. There is only slight relative increase in the outputs of the apical part of the array at 85 db relative to the lower intensity patterns.

region between 65 and 85 db, the region of onset of nonlinearity. According to Fig. 3.10.A the intensity functions of the different electrodes become slightly different. At 11 and 12 linearity persists, at the remaining electrodes slight deviation from linearity is noticeable. Thus it is clear that the corresponding $H(x)$ underwent slight alteration in shape between *65 and 85 db. Nevertheless, this change in* shape must have been very small indeed. In Fig. 3.10.B the 35, 65 and 85 db patterns were redrawn on a linear amplitude scale. In the drawing the output 1 is given equal height in the three patterns in order to facilitate comparison of their shapes. It is obvious that the shapes are almost identical with only a slight growth in the distant electrodes at 85 db relative to the lower intensity patterns.

We can safely assume that the shape of $H(x)''$ is a close approximation to the shape of the hair-cell output pattern for sound pressures up to 90 db SPL. The frequency response curve deduced from $H(x)''$ at 90 db is therefore also valid at lower SPLs.

Inversion of the spatial filter operation

The mathematical method used so far was essentially a graphical procedure. We assumed *a certain pattern* $H(x)'$ we calculated the corresponding theoretical $CM(x)$ and compared it with experimental curves. In the event of a good agreement between the theoretical $CM(x)$ and an experimental CM pattern we postulated $H(x)$ as a close approximation to the real hair-cell output pattern along the basilar membrane. This way of operation proved very successful *and our data suggest an* $H(x)''$ *fully* compatible with the information about the mechanical behaviour of the membrane in the basal turn.

However the graphical method is awkward and time-consuming and therefore not well suited for the analytical treatment of large amounts of data obtainable with the multi electrode technique. This applies especially to the studies of variations in the shape of "$H(x)$" in the nonlinear region of hair-cell operators. It also applies to the investigation of alterations of hair-cell output after overstimulation. We found it therefore highly desirable to develop a way of deducing analytically from any measured CM pattern the corresponding "$H(x)$". Given the function $H(x) = f(\mathrm{CM}(x), W(x))$ explicit in $H(x)$, we were theoretically speaking in a position to derive from any measured $\mathrm{CM}(x)$ the corresponding $H(x)$. In view of this situation my colleague H. F. Ross, suggested matrix inversion as one of the possible ways to derive $H(x)$ directly from the data. In fact it was this original formulation of the deduction problem in matrix form which demonstrated mathematically the possibility for obtaining $H(x)$. Yet, for practical reasons matrix inversion is not the most suitable mathematical technique. It cannot be written in closed form, hence it does not display in explicit fashion the connections involved in the deduction process. From the point of view of the experimenter it is important to know explicitly these connections because they allow the judgement over the practicability of the deduction.

The spatial filter operation can be inverted mathematically and $H(x)$ can be expressed explicitly as a function of $\mathrm{CM}(x)$ and $W(x)$. I obtained the expression for $H(x)$ by means of the following mathematical steps

Given $\quad \mathrm{CM}(x) = H(x) * W(x) \qquad (1)$

and $\quad W(x) = \exp(-\lambda|x|) \qquad (6)$

By taking the Fourier Transform of equation (1)

$$F_{\mathrm{CM}} = F_H \cdot F_W$$

(F denotes the Fourier Transform)

thus $\quad F_H = \dfrac{F_{\mathrm{CM}}}{F_W} \qquad (1a)$

The Fourier transform of equation (6):

$$F_W = \frac{2\lambda}{\lambda^2 + \nu^2} \qquad (6a)$$

where ν is the independent variable in the Fourier domain. It denotes spatial frequency. By inserting (6 a) into (1 a)

$$F_H = F_{\mathrm{CM}}\left[\frac{\lambda^2 + \nu^2}{2\lambda}\right] = \frac{\lambda}{2} F_{\mathrm{CM}} + \frac{\nu^2}{2\lambda} F_{\mathrm{CM}} \qquad (1b)$$

By taking the Inverse Fourier Transform of (1 b) we obtain

$$H(x) = \frac{\lambda}{2}\mathrm{CM}(x) - \frac{1}{2\lambda}\frac{d^2\mathrm{CM}(x)}{dx^2} \qquad (1\,A)$$

(In the case of an asymmetrical weighting function with different attenuation values in the apical and basal directions $H(x)$ takes a slightly different form

with

$$W(x) = \begin{cases} \exp(-\lambda_1|x|) & x < 0 \\ \exp(-\lambda_2|x|) & x > 0 \end{cases}$$

it follows

$$H(x) = \frac{\lambda_1 \lambda_2}{\lambda_1 + \lambda_2}\mathrm{CM}(x) + \frac{\lambda_1 - \lambda_2}{\lambda_1 + \lambda_2}\frac{d\mathrm{CM}(x)}{dx} - \frac{1}{\lambda_1 + \lambda_2}\frac{d^2\mathrm{CM}(x)}{dx^2}$$

This expression was obtained in the same way as (1 A). In the case $\lambda_1 = \lambda_2 = \lambda$ equation (1 A) results. Since von Békésy reported symmetrical attenuation we only considered (1 A).)

In equation (1 A) $H(x)$ appears as the linear combination of $\mathrm{CM}(x)$ and $\mathrm{CM}(x)''$. For a large λ, i.e. strong electrical attenuation of signal along the cochlea, we can approximate equation (1 A) by the expression in (1 B)

$$H(x) \approx \frac{\lambda}{2}\mathrm{CM}(x), \quad \lambda > 1 \qquad (1\,B)$$

This is an expression valid in the absence of spatial filtering. Due to strong longitudinal attenuation there is no interference of hair cell outputs along the cochlear ducts. In such a situation an electrode output at x directly reflects the corresponding hair-cell activity at x. Equation (1 *B*) is also an approximation in the case of a small second spatial derivative of $CM(x)$:

$$H(x) \approx \frac{\lambda}{2} CM(x), \quad CM(x)'' < 1 \qquad (1\,B)$$

This expression of $H(x)$ applies to some extent to the basalmost part of the excitation pattern along the membrane at low stimulus frequencies. The wavelength is relatively long in this part and negative interference, phase cancellation of hair-cell outputs will be negligible. In the case of small longitudinal attenuation we may approximate equation (1 *A*) by (1 *C*):

$$H(x) \approx -\frac{1}{\lambda} CM(x)'' \quad \lambda < 1 \qquad (1\,C)$$

In this case it is the second spatial derivative of $CM(x)$ which resembles $H(x)$ directly and $CM(x)$ is not itself an index of $H(x)$. Clearly such a situation requires the recording of the second spatial derivative of $CM(x)$ as a measure of $H(x)$. Widely spaced electrodes are completely inadequate because they do not provide any information about the local curvature of the CM pattern—information needed for the calculation of the second derivative. Only by means of closely spaced electrodes do we obtain sufficient numerical information about the shape of the CM pattern to allow the derivation of $CM(x)''$.

In reality λ is neither very much smaller nor very much greater than 1: it has a value of $\lambda = 0.69$ corresponding to a signal attenuation of 6 db per mm. For the deduction of $H(x)$ from experimental CM curves we have to use equation (1 *A*).

$$H(\ ) = 0.35\,CM(\ ) - 0.72\,CM(x) \qquad (1\,A)$$

Mathematically speaking, equation (1 *A*) poses no great problems; it is a neat and simple expression for the relationship between $H(x)$ and $CM(x)$. It will, however, turn out that the requirements on experimental data, implicit in (1 *A*), are too demanding for the practical application of the inverse spatial filter operation. This is due to the second derivative term in (1 *A*) which magnifies any slight irregularity in the measured CM pattern. We can demonstrate the strong influence of $CM(x)''$ on $H(x)$ in a simple hypothetical case. In Fig. 3.11 we considered the shape of $H(x)$ resulting from a hypothetical $CM(x)$ given as a straight line

$$CM(x) = -\frac{A}{B}(x - B) \qquad (10\,a)$$

The second derivative of (10 *a*) is zero and we obtain as $H(x)$ with equation (1 *A*):

$$H(x) = -\frac{\lambda}{2}\frac{A}{B}(x - B) \qquad (10\,b)$$

The curves (10 *a*) and (10 *b*) are shown in Fig. 3.11.I and Fig. 3.11.II respectively ($\lambda = 0.69$). Let us assume that $CM(x)$ was obtained with a hypothetical set of electrodes situated along x with an interelectrode distance $\Delta x = 0.15$ mm (this is the distance between electrodes in the electrode array). Assume further that the electrode at x_e records a potential which deviates from the straight line by 1 %. We can calculate the influence of this 1 per cent error in $CM(x)$ on the shape of $H(x)$ by means of equation (1 *A*). The second derivative was obtained numerically with the formula.

$$CM(x_e)'' = \frac{CM(x_{e-1}) - 2\,CM(x_e) + CM(x_{e}\ )}{\Delta x^2}$$

It can be seen from Fig. 3.11.II that the slight deviation in $CM(x)$ causes a drastic alteration of the shape of $H(x)$. Thus the 1 % error at x_e in $CM(x)$ causes an error of -60 % at x_{e-}, $+183$ % at x and -182 % at x_{e+}. Due to the small error in $CM(x)$ the resulting $H(x)$ undergoes large deflections around the line given by (10 *b*). The wavelength of the deflections is very short and corresponds to a high 'spatial frequency'.

However the graphical method is awkward and time-consuming and therefore not well suited for the analytical treatment of large amounts of data obtainable with the multi electrode technique. This applies especially to the studies of variations in the shape of "$H(x)$" in the nonlinear region of hair-cell operators it also applies to the investigation of alterations of hair-cell output after overstimulation We found it therefore highly desirable to develop a way of deducing analytically from any measured CM pattern the corresponding "$H(x)$" Given the function $H(x) = f(\mathrm{CM}(x)\ W(x))$ explicit in $H(x)$ we were theoretically speaking in a position to derive from any measured $\mathrm{CM}(x)$ the corresponding $H(x)$ In view of this situation my colleague H. F Ross, suggested matrix inversion as one of the possible ways to derive $H(x)$ directly from the data. In fact it was this original formulation of the deduction problem in matrix form which demonstrated mathematically the possibility for obtaining $H(x)$ Yet for practical reasons matrix inversion is not the most suitable mathematical technique It cannot be written in closed form hence it does not display in explicit fashion the connections involved in the deduction process. From the point of view of the experimenter it is important to know explicitly these connections because they allow the judgement over the practicability of the deduction.

The spatial filter operation can be inverted mathematically and $H(x)$ can be expressed explicitly as a function of $\mathrm{CM}(x)$ and $W(x)$ I obtained the expression for $H(x)$ by means of the following mathematical steps:

$$\text{Given} \quad \mathrm{CM}(x) = H(x) * W(x) \tag{1}$$

$$\text{and} \quad W(x) = \exp(-\lambda|x|) \tag{6}$$

By taking the Fourier Transform of equation (1)

$$F_{CM} = F_H\ F_W$$

(F denotes the Fourier Transform)

thus

$$F_H = \frac{F_{CM}}{F_W} \tag{1 a}$$

The Fourier transform of equation (6):

$$F_W = \frac{2\lambda}{\lambda^2 + \nu^2} \tag{6 a}$$

where ν is the independent variable in the Fourier domain it denotes spatial frequency By inserting (6 a) into (1 a)

$$F_H = F_{CM}\left[\frac{\lambda^2 + \nu^2}{2\lambda}\right] = \frac{\lambda}{2} F_{CM} + \frac{\nu^2}{2\lambda} F_{CM} \tag{1 b}$$

By taking the Inverse Fourier Transform of (1 b) we obtain

$$H(x) = \frac{\lambda}{2}\mathrm{CM}(x) - \frac{1}{2\lambda}\frac{d^2\mathrm{CM}(x)}{dx^2} \tag{1 A}$$

(In the case of an asymmetrical weighting function with different attenuation values in the apical and basal directions $H(x)$ takes a slightly different form

with

$$W(x) = \begin{cases} \exp(-\lambda_1|x|) & x < 0 \\ \exp(-\lambda_2|x|) & x > 0 \end{cases}$$

it follows

$$H(x) = \frac{\lambda_1 \lambda_2}{\lambda_1 + \lambda_2}\mathrm{CM}(x) + \frac{\lambda_1 - \lambda_2}{\lambda_1 + \lambda_2}\frac{d\mathrm{CM}(x)}{dx} - \frac{1}{\lambda_1 + \lambda_2}\frac{d^2\mathrm{CM}(x)}{dx^2}$$

This expression was obtained in the same way as (1 A) In the case $\lambda_1 = \lambda_2 = \lambda$ equation (1 A) results. Since von Békésy reported symmetrical attenuation we only considered (1 A))

In equation (1 A) $H(x)$ appears as the linear combination of $\mathrm{CM}(x)$ and $\mathrm{CM}(x)''$ For a large λ, i e strong electrical attenuation of signal along the cochlea, we can approximate equation (1 A) by the expression in (1 B):

$$H(x) \approx \frac{\lambda}{2}\mathrm{CM}(x) \quad \lambda \gg 1 \tag{1 B}$$

This is an expression valid in the absence of spatial filtering. Due to strong longitudinal attenuation there is no interference of hair cell outputs along the cochlear ducts. In such a situation an electrode output at x directly reflects the corresponding hair-cell activity at x. Equation (1 *B*) is also an approximation in the case of a small second spatial derivative of CM(x):

$$H(x) \approx \frac{\lambda}{2} \mathrm{CM}(x), \quad \mathrm{CM}(x)'' \ll 1 \qquad (1\,B)$$

This expression of $H(x)$ applies to some extent to the basalmost part of the excitation pattern along the membrane at low stimulus frequencies. The wavelength is relatively long in this part and negative interference, phase cancellation of hair-cell outputs will be negligible. In the case of small longitudinal attenuation we may approximate equation (1 *A*) by (1 *C*):

$$H(x) \approx -\frac{1}{2\lambda} \mathrm{CM}(x)'' \qquad \lambda \ll 1 \qquad (1\,C)$$

In this case it is the second spatial derivative of CM(x) which resembles $H(x)$ directly and CM(x) is not itself an index of H(x). Clearly such a situation requires the recording of the second spatial derivative of CM(x) as a measure of $H(x)$. Widely spaced electrodes are completely inadequate because they do not provide any information about the local curvature of the CM pattern—information needed for the calculation of the second derivative. Only by means of closely spaced electrodes do we obtain sufficient numerical information about the shape of the CM pattern to allow the derivation of CM(x)''.

In reality λ is neither very much smaller nor very much greater than 1: it has a value of $\lambda = 0.69$ corresponding to a signal attenuation of 6 db per mm. For the deduction of $H(x)$ from experimental CM curves we have to use equation (1 *A*):

$$H(x) = 0.35\,\mathrm{CM}(x) - 0.72\,\mathrm{CM}(x)'' \qquad (1\,A)$$

Mathematically speaking, equation (1 *A*) poses no great problems, it is a neat and simple expression for the relationship between $H(x)$ and CM(x). It will, however, turn out that the requirements on experimental data, implicit in (1 *A*), are too demanding for the practical application of the inverse spatial filter operation. This is due to the second derivative term in (1 *A*) which magnifies any slight irregularity in the measured CM pattern. We can demonstrate the strong influence of CM(x)'' on $H(x)$ in a simple hypothetical case. In Fig. 3.11 we considered the shape of $H(x)$ resulting from a hypothetical CM(x) given as a straight line:

$$\mathrm{CM}(x) = -\frac{A}{B}(x - B) \qquad (10\,a)$$

The second derivative of (10 *a*) is zero and we obtain as $H(x)$ with equation (1 *A*):

$$H(x) = -\frac{\lambda}{2}\frac{A}{B}(x - B) \qquad (10\,b)$$

The curves (10 *a*) and (10 *b*) are shown in Fig. 3.11 I and Fig. 3.11 II respectively ($\lambda = 0.69$). Let us assume that CM(x) was obtained with a hypothetical set of electrodes situated along x with an interelectrode distance $\Delta x = 0.15$ mm (this is the distance between electrodes in the electrode array). Assume further that the electrode at x_r records a potential which deviates from the straight line by 1%. We can calculate the influence of this 1 per cent error in CM(x) on the shape of $H(x)$ by means of equation (1 *A*). The second derivative was obtained numerically with the formula:

$$\mathrm{CM}(x_r)'' = \frac{CM(x_{r-1}) - 2\,CM(x_r) + \mathrm{CM}(x_{r+1})}{\Delta x^2}$$

It can be seen from Fig. 3.11 II that the slight deviation in CM(x) causes a drastic alteration of the shape of $H(x)$. Thus the 1% error at x_r in CM(x) causes an error of −60% at x_{r-1}, +183% at x_r and −182% at x_{r+1}. Due to the small error in CM(x) the resulting $H(x)$ undergoes large deflections around the line given by (10 *b*). The wavelength of the deflections is very short and corresponds to a high 'spatial frequency'.

However the graphical method is awkward and time-consuming and therefore not well suited for the analytical treatment of large amounts of data obtainable with the multi electrode technique This applies especially to the studies of variations in the shape of "$H(x)$" in the nonlinear region of hair-cell operators it also applies to the investigation of alterations of hair-cell output after overstimulation We found it therefore highly desirable to develop a way of deducing analytically from any measured CM pattern the corresponding "$H(x)$" Given the function $H(x) = f(\mathrm{CM}(x)\ W(x))$ explicit in $H(x)$ we were theoretically speaking in a position to derive from any measured $\mathrm{CM}(x)$ the corresponding $H(x)$ In view of this situation my colleague H. F Ross, suggested matrix inversion as one of the possible ways to derive $H(x)$ directly from the data. In fact it was this original formulation of the deduction problem in matrix form which demonstrated mathematically the possibility for obtaining $H(x)$ Yet, for practical reasons matrix inversion is not the most suitable mathematical technique It cannot be written in closed form hence it does not display in explicit fashion the connections involved in the deduction process From the point of view of the experimenter it is important to know explicitly these connections because they allow the judgement over the practicability of the deduction

The spatial filter operation can be inverted mathematically and $H(x)$ can be expressed explicitly as a function of $\mathrm{CM}(x)$ and $W(x)$ I obtained the expression for $H(x)$ by means of the following mathematical steps

Given $$\mathrm{CM}(x) = H(x) * W(x) \qquad (1)$$

and $$W(x) = \exp(-\lambda|x|) \qquad (6)$$

By taking the Fourier Transform of equation (1)

$$F_{\mathrm{CM}} = F_H\ F_W$$

(F denotes the Fourier Transform)

thus $$F_H = \frac{F_{\mathrm{CM}}}{F_W} \qquad (1\,a)$$

The Fourier transform of equation (6)

$$F_W = \frac{2\lambda}{\lambda^2 + \nu^2} \qquad (6\,a)$$

where ν is the independent variable in the Fourier domain It denotes spatial frequency By inserting (6 a) into (1 a)

$$F_H = F_{\mathrm{CM}}\left[\frac{\lambda^2+\nu^2}{2\lambda}\right] = \frac{\lambda}{2}F_{\mathrm{CM}} + \frac{\nu^2}{2\lambda}F_{\mathrm{CM}} \qquad (1\,b)$$

By taking the Inverse Fourier Transform of (1 b) we obtain.

$$H(x) = \frac{\lambda}{2}\mathrm{CM}(x) - \frac{1}{2\lambda}\frac{d^2\mathrm{CM}(x)}{dx^2} \qquad (1\,A)$$

(In the case of an asymmetrical weighting function with different attenuation values in the apical and basal directions $H(x)$ takes a slightly different form

with

$$W(x) = \begin{cases} \exp(-\lambda_1|x|) & x \leq 0 \\ \exp(-\lambda_2|x|) & x > 0 \end{cases}$$

it follows

$$H(x) = \frac{\lambda_1\lambda_2}{\lambda_1+\lambda_2}\mathrm{CM}(x) + \frac{\lambda_1-\lambda_2}{\lambda_1+\lambda_2}\frac{d\mathrm{CM}(x)}{dx} - \frac{1}{\lambda_1+\lambda_2}\frac{d^2\mathrm{CM}(x)}{dx^2}$$

This expression was obtained in the same way as (1 A) In the case $\lambda_1 = \lambda_2 = \lambda$ equation (1 A) results. Since von Békésy reported symmetrical attenuation we only considered (1 A))

In equation (1 A) $H(x)$ appears as the linear combination of $\mathrm{CM}(x)$ and $\mathrm{CM}(x)$ For a large λ, i e strong electrical attenuation of signal along the cochlea we can approximate equation (1 1) by the expression in (1 B):

$$H(x) \approx \frac{\lambda}{2}\mathrm{CM}(x) \quad \lambda \gg 1 \qquad (1\,B)$$

This is an expression valid in the absence of spatial filtering. Due to strong longitudinal attenuation *there is no* interference of hair cell outputs along the cochlear ducts. In such a situation an electrode output at x directly *reflects the corresponding* hair-cell activity at x. Equation (*1 B*) is also an approximation in the case of a small second spatial derivative of $CM(x)$:

$$H(x) \approx \frac{\lambda}{2} CM(x), \quad CM(x)'' < 1 \qquad (1\,B)$$

This expression of $H(x)$ applies to some extent to the basalmost part of the excitation pattern along the membrane at low stimulus frequencies. The wavelength is relatively long in this part and negative interference, phase cancellation of hair-cell *outputs will be negligible.* In the case of small longitudinal attenuation we may approximate equation (1 *A*) by (1 C):

$$H(x) \approx -\frac{1}{2\lambda} CM(x) \qquad \lambda < 1 \qquad (1\,C)$$

In this case it is the *second* spatial derivative of CM(x) which resembles $H(x)$ directly and CM(x) is not itself an index of H(x). Clearly *such a situation requires the recording of* the second spatial derivative of CM(x) as a measure of $H(x)$. Widely spaced electrodes are *completely inadequate* because they do not provide any information about the local curvature of the CM pattern—information needed for the calculation of the second derivative. Only by means of closely spaced electrodes do we obtain sufficient numerical information about the shape of the CM pattern to allow the derivation of $CM(x)''$.

In reality λ is neither very much smaller nor very much greater than 1. It has a value of $\lambda = 0.69$ corresponding to a signal attenuation of 6 db per mm. For *the* deduction of $H(x)$ from experimental CM curves we have to use equation (1 *A*):

$$H(x) = 0.35\,CM(x) - 0.72\,CM(x)'' \qquad (1\,A)$$

Mathematically speaking, equation (1 *A*) poses no great problems, it is a neat and simple expression for the relationship between $H(x)$ and $CM(x)$. *It will, however turn out that the* requirements on experimental data, implicit in (1 *A*), are too demanding for the practical application of the inverse spatial filter operation. This is due to the second derivative term in (1 *A*) which magnifies any slight irregularity in the measured CM pattern. We can demonstrate the strong influence of $CM(x)''$ on $H(x)$ in a simple hypothetical case. In Fig. 3.11 we considered the shape of $H(x)$ resulting from a hypothetical CM(x) given as a straight line,

$$CM(x) = -\frac{A}{B}(x - B) \qquad (10\,a)$$

The second derivative of (10 *a*) is zero and we obtain as $H(x)$ with equation (1 *A*):

$$H(x) = -\frac{\lambda}{2}\frac{A}{B}(x - B) \qquad (10\,b)$$

The curves (10 *a*) and (10 *b*) are shown in Fig. 3.11.I and Fig. 3.11.II respectively ($\lambda = 0.69$). Let us assume that CM(x) was obtained with a hypothetical set of electrodes situated along x *with an interelectrode distance* $\Delta x = 0.15$ mm (this is the distance between electrodes in the electrode array). Assume further that the electrode at x records a potential which deviates from the straight line by 1%. We can calculate the influence of this 1 per cent error in CM(x) on the shape of $H(x)$ by means of equation (1 *A*). The second derivative was obtained numerically with the formula,

$$CM(x_k)'' = \frac{CM(x_{k-1}) - 2\,CM(x_k) + CM(x_{k+1})}{\Delta x^2}$$

It can be seen from Fig. 3.11.II that the slight deviation in $CM(x)$ causes a drastic alteration of the shape of $H(x)$. Thus the 1% *error* at x_k in CM(x) causes an error of -60% at x_{k-1}, $+183\%$ at x_k and -182% at x_{k+1}. Due to the small error in $CM(x)$ the resulting $H(x)$ undergoes large deflections around *the line* given by (10 *b*). *The* wavelength of the deflections is very short and corresponds to a high 'spatial frequency'.

However the graphical method is awkward and time-consuming and therefore not well suited for the analytical treatment of large amounts of data obtainable with the multi electrode technique This applies especially to the studies of variations in the shape of "$H(x)$" in the nonlinear region of hair-cell operators it also applies to the investigation of alterations of hair-cell output after overstimulation We found it therefore highly desirable to develop a way of deducing analytically from any measured CM pattern the corresponding $H(x)$" Given the function $H(x) = f(\mathrm{CM}(x)\ W(x))$ explicit in $H(x)$ we were theoretically speaking in a position to derive from any measured $\mathrm{CM}(x)$ the corresponding $H(x)$ In view of this situation my colleague H. F Ross, suggested matrix inversion as one of the possible ways to derive $H(x)$ directly from the data. In fact it was this original formulation of the deduction problem in matrix form which demonstrated mathematically the possibility for obtaining $H(x)$ Yet for practical reasons matrix inversion is not the most suitable mathematical technique It cannot be written in closed form hence it does not display in explicit fashion the connections involved in the deduction process. From the point of view of the experimenter it is important to know explicitly these connections because they allow the judgement over the practicability of the deduction.

The spatial filter operation can be inverted mathematically and $H(x)$ can be expressed explicitly as a function of $\mathrm{CM}(x)$ and $W(x)$ I obtained the expression for $H(x)$ by means of the following mathematical steps:

Given $\quad \mathrm{CM}(x) = H(x) * W(x) \qquad (1)$

and $\quad W(x) = \exp(-\lambda|x|) \qquad (6)$

By taking the Fourier Transform of equation (1)

$$F_{\mathrm{CM}} = F_H\ F_W$$

(F denotes the Fourier Transform)

thus $\quad F_H = \dfrac{F_{\mathrm{CM}}}{F_W} \qquad (1a)$

The Fourier transform of equation (6):

$$F_W = \frac{2\lambda}{\lambda^2 + \nu^2} \qquad (6a)$$

where ν is the independent variable in the Fourier domain It denotes spatial frequency By inserting (6 a) into (1 a)

$$F_H = F_{\mathrm{CM}}\left[\frac{\lambda^2 + \nu^2}{2\lambda}\right] = \frac{\lambda}{2}F_{\mathrm{CM}} + \frac{\nu^2}{2\lambda}F_{\mathrm{CM}} \qquad (1b)$$

By taking the Inverse Fourier Transform of (1 b) we obtain

$$H(x) = \frac{\lambda}{2}\mathrm{CM}(x) - \frac{1}{2\lambda}\frac{d^2\mathrm{CM}(x)}{dx^2} \qquad (1A)$$

(In the case of an asymmetrical weighting function with different attenuation values in the apical and basal directions $H(x)$ takes a slightly different form

with

$$W(x) = \begin{matrix} \exp(-\lambda_1|x|) & x < 0 \\ \exp(-\lambda_2|x|) & x > 0 \end{matrix}$$

it follows

$$H(x) = \frac{\lambda_1\lambda_2}{\lambda_1 + \lambda_2}\mathrm{CM}(x) + \frac{\lambda_1 - \lambda_2}{\lambda_1 + \lambda_2}\frac{d\mathrm{CM}(x)}{dx} - \frac{1}{\lambda_1 + \lambda_2}\frac{d^2\mathrm{CM}(x)}{dx^2}$$

This expression was obtained in the same way as (1 A) In the case $\lambda_1 = \lambda_2 = \lambda$ equation (1 A) results. Since von Békésy reported symmetrical attenuation we only considered (1 A))

In equation (1 A) $H(x)$ appears as the linear combination of $\mathrm{CM}(x)$ and $\mathrm{CM}(x)$ For a large λ i e strong electrical attenuation of signal along the cochlea we can approximate equation (1 A) by the expression in (1 B)

$$H(x) \approx \frac{\lambda}{2}\mathrm{CM}(x) \quad \lambda > 1 \qquad (1B)$$

This is an expression valid in the absence of spatial filtering. Due to strong longitudinal attenuation there is no interference of hair cell outputs along the cochlear ducts. In such a situation an electrode output at x directly reflects the corresponding hair-cell activity at x. Equation (1 *B*) is also an approximation in the case of a small second spatial derivative of CM(x):

$$H(x) \approx \frac{\lambda}{2} \mathrm{CM}(x) \quad \mathrm{CM}(x)'' \ll 1 \qquad (1\,B)$$

This expression of $H(x)$ applies to some extent to the basalmost part of the excitation pattern along the membrane at low stimulus frequencies. The wavelength is relatively long in this part and negative interference, phase cancellation of hair-cell outputs will be negligible. In the case of small longitudinal attenuation we may approximate equation (1 *A*) by (1 *C*):

$$H(x) \approx -\frac{1}{\lambda} \mathrm{CM}(x)'' \quad \lambda < 1 \qquad (1\,C)$$

In this case it is the second spatial derivative of CM(x) which resembles $H(x)$ directly and CM(x) is not itself an index of H(x). Clearly such a situation requires the recording of the second spatial derivative of CM(x) as a measure of $H(x)$. Widely spaced electrodes are completely inadequate because they do not provide any information about the local curvature of the CM pattern—information needed for the calculation of the second derivative. Only by means of closely spaced electrodes do we obtain sufficient numerical information about the shape of the CM pattern to allow the derivation of CM(x)''.

In reality λ is neither very much smaller nor very much greater than 1: it has a value of $\lambda = 0.69$ corresponding to a signal attenuation of 6 db per mm. For the deduction of $H(x)$ from experimental CM curves we have to use equation (1 *A*):

$$H(x) = 0.35\,\mathrm{CM}(x) - 0.72\,\mathrm{CM}(x)'' \qquad (1\,A)$$

Mathematically speaking, equation (1 *A*) poses no great problems, it is a neat and simple expression for the relationship between $H(x)$ and CM(x). It will, however, turn out that the requirements on experimental data, implicit in (1 *A*), are too demanding for the practical application of the inverse spatial filter operation. This is due to the second derivative term in (1 *A*) which magnifies any slight irregularity in the measured CM pattern. We can demonstrate the strong influence of CM(x)'' on $H(x)$ in a simple hypothetical case. In Fig. 3.11 we considered the shape of $H(x)$ resulting from a hypothetical CM(x) given as a straight line:

$$\mathrm{CM}(x) = -\frac{A}{B}(x - B) \qquad (10\,a)$$

The second derivative of (10 *a*) is zero and we obtain as $H(x)$ with equation (1 *A*):

$$H(x) = -\frac{\lambda}{2}\frac{A}{B}(x - B) \qquad (10\,b)$$

The curves (10 *a*) and (10 *b*) are shown in Fig. 3.11.I and Fig. 3.11.II respectively ($\lambda = 0.69$). Let us assume that CM(x) was obtained with a hypothetical set of electrodes situated along x with an interelectrode distance $\Delta x = 0.15$ mm (this is the distance between electrodes in the electrode array). Assume further that the electrode at x_r records a potential which deviates from the straight line by 1%. We can calculate the influence of this '1 per cent error' in CM(x) on the shape of $H(x)$ by means of equation (1 *A*). The second derivative was obtained numerically with the formula:

$$\mathrm{CM}(x_r)'' = \frac{\mathrm{CM}(x_{r-1}) - 2\,\mathrm{CM}(x_r) + \mathrm{CM}(x_{r+1})}{\Delta x^2}$$

It can be seen from Fig. 3.11.II that the slight deviation in CM(x) causes a drastic alteration of the shape of $H(x)$. Thus the 1% error at x_r in CM(x) causes an error of -60% at x_{r-1}, $+183\%$ at x_r, and -182% at x_{r+1}. Due to the small error in CM(x) the resulting $H(x)$ undergoes large deflections around the line given by (10 *b*). The wavelength of the deflections is very short and corresponds to a high 'spatial frequency'.

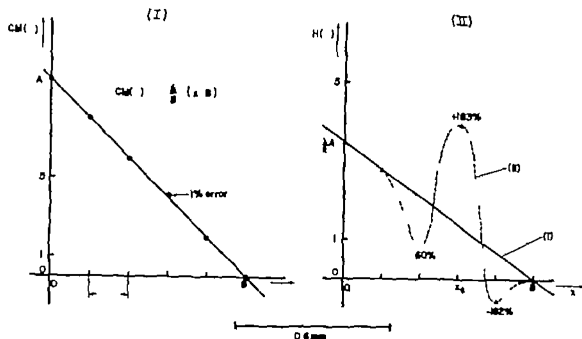

Fig 3 11 Application of the inverse spatial filter operation to a hypothetical CM(*x*).
I. CM(*x*) assumed as

$$CM(x) = -\frac{A}{B}(x - B) \qquad (10a)$$

II The corresponding $H(x)$ has the form

$$H(x) = -\frac{\lambda}{2}\frac{A}{B}(x - B) \qquad (10b)$$

$H(x)$ is drawn in II for $\lambda = 0\ 69$ and it is marked *I* (——) Suppose CM(*x*) was measured with a hypothetical set of electrodes with an interelectrode distanc $\Delta x = 0\ 15$ mm equal to the distance between electrode in the real electrode array Suppose further that elec trode at x_i records an 'error potential' which deviate from the straight line by 1% This 1% error produce large deflections in the deduced $H(x)$ (II, – –) around the ideal straight line. The deviation by 1% at x in $CM(x)$ causes large deviations in $H(x)$: at x_{-1} it is -60% at x $+183\%$ and at x_{+1} it is -182% Thus small ripples in any given CM(*x*) produce large deflec tions of short wavelength in the deduced $H(x)$

This result is somewhat disturbing, apart from the fact that it demonstrates the im practicability of the direct deduction of $H(x)$ from CM(x) We may explain the necessity of this result in a simple model based upon the analogy between spatial filtering and linear electrical filters. In Fig 3 12 $H_i(x)$ and CM (x) represent the input and output functions of the

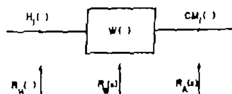

Fig 3.12 Model for the inverse spatial filtering operation. In the ideal situation the input function H (x) can be reconstructed from the output function $CM_i(x)$ In reality 'ripple noise' is present.
$R_A(x)$: ripple noise in the recording system.
R (x): ripple noise due to inadequate $W(x)$.
$R_H(x)$: ripple noise present in the input function $H(x)$.

spatial filter in the ideal situation with no disturbing effects present.

$W(x)$ denotes the spatial impulse response of the spatial filter Since the Fourier Transform of $W(x)$ equals the spatial frequency response of the spatial filter we can write according to equation (6 *a*)

$$F_W = \frac{2\lambda}{\lambda^2 + \nu^2} \qquad (6a)$$

It follows from (6 *a*) that high spatial fre quencies ν are much more attenuated than low ones or when expressed in terms of wave length that short wavelengths in $H(x)$ are much more attenuated than long wavelengths. Thus the low spatial frequency components of H (x) will be dominating the appearance of the pattern $CM_i(x)$ and high spatial frequency components will just lead to slight 'ripple like' undulations. Nevertheless the input $H_i(x)$ can

be recovered unequivocally from $CM_i(x)$ by virtue of the second spatial derivative of $CM_i(x)$ which enhances the ripples of short wavelength, i.e. of high spatial frequency.

However in the real situation the reconstruction of the input $H_i(x)$ from experimental data runs into difficulties because we encounter small irregularities in the output pattern. Let us call these irregularities spatial 'ripple noise' $R(x)$. Thus the experimental CM pattern can be represented as the sum of the ideal pattern $CM_i(x)$ and $R(x)$.

$$CM(x) = CM_i(x) + R(x)$$

When $R(x)$ has wavelengths in the order of magnitude of the short wavelengths in the input pattern it is clearly impossible to obtain an unambiguous reconstruction of the input pattern from the output data. Thus if we want to deduce from experimental CM patterns the corresponding hair-cell output pattern we face the problem of having to identify $R(x)$ or in other words, we must distinguish between ripple noise $R(x)$ and the ideal pattern $CM_i(x)$. This cannot be an easy task, because all we have at hand is $CM(x)$.

The identification of small ripples in experimental CM patterns as ripple noise $R(x)$ would be quite simple provided the ripples occurred at random. Thus if slight undulations in CM patterns are not reproducible within one experimental session and in different experiments we have a certain right to disregard ripples in any one particular CM pattern. By fitting the CM patterns with smooth curves, omitting irregularities of short wavelength we could approximate to $CM_i(x)$ and proceed to calculate $H_i(x)$.

However the ripple patterns shown by our recordings exhibit a high degree of stability and reproducibility. They were found consistently in all preparations. The ripples occurred usually in the regions centered around electrodes 2, 5, 9. This gives an average ripple length of approximately 0.5 mm. It is interesting to note that the ripple length did not change significantly with stimulus frequency. By using

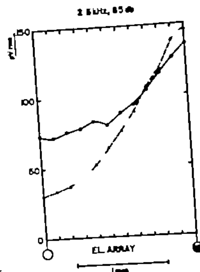

Fig. 3.13 CM amplitude distribution at 2.5 kHz, 85 db measured before and after overstimulation with 13 kHz, 130 db for 3 min. While the pre-traumatic curve contains small ripples the post-traumatic curve is very smooth. This indicates that the ripples are not dependent on the recording system, i.e. they are not introduced by nonuniformity in electrode channels. $R_s(x)$ can be excluded as source for ripple noise. ●—● 2.5 kHz CM amplitude pattern before overstimulation with 13 kHz tone; ▲—▲ 2.5 kHz CM amplitude pattern after overstimulation with 13 kHz tone.

equation (1 A) we calculated patterns $H(x)$ which had more than one maximum in the envelope: the ripple pattern seen in the experimental CM patterns appeared strongly enhanced in the deduced $H(x)$.

For the discussion of the question whether the ripples in the experimental CM pattern represent a real phenomenon or just an artefact it is convenient to distinguish three group of possible sources for the ripples (see Fig 3.12). $R_H(x)$ denotes the ripple noise occurrin in the input signal $H(x)$ itself. $R_W(x)$ designate ripple noise due to the inadequacy of the spatial filter function $W(x)$. $R_s(x)$ designate ripple noise due to imperfection in the recording system, as for instance slight nonuniformity of different electrode channels.

$R_s(x)$: We can rule out $R_s(x)$ on the basis o the following observation. Fig. 3.13 shows th

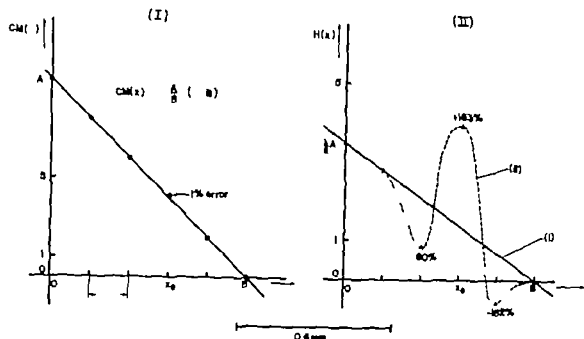

Fig 3 11 Application of the inverse spatial filter operation to a hypothetical CM(x)
I. CM(x) assumed as.

$$\mathrm{CM}(x) = -\frac{A}{B}(x-B) \qquad (10\,a)$$

II The corresponding $H(x)$ has the form.

$$H(x) = -\frac{\lambda}{2}\frac{A}{B}(x-B) \qquad (10\,b)$$

$H(x)$ is drawn in II for $\lambda = 0.69$ and it is marked *I* (——) Suppose CM(x) was measured with a hypothetical set of electrodes with an interelectrode distance $\Delta x = 0.15$ mm equal to the distance between electrodes in the real electrode array Suppose further that electrode at x records an error potential' which deviates from the straight line by 1% This 1% error produces large deflections in the deduced $H(x)$ (II, --) around the ideal straight line. The deviation by 1% at x_0 in CM(x) causes large deviations in $H(x)$: at x_{-} it is −60% at x +183% and at x it is −182% Thus small ripples in any given CM(x) produce large deflections of short wavelength in the deduced $H(x)$.

This result is somewhat disturbing apart from the fact that it demonstrates the impracticability of the direct deduction of $H(x)$ from CM(x) We may explain the necessity of this result in a simple model based upon the analogy between spatial filtering and linear electrical filters. In Fig 3 12 $H(x)$ and $CM_i(x)$ represent the input and output functions of the spatial filter in the ideal situation with no disturbing effects present

$W(x)$ denotes the spatial impulse response of the spatial filter Since the Fourier Transform of $W(x)$ equals the spatial frequency response of the spatial filter we can write according to equation (6 a)

$$F_W = \frac{2\lambda}{\lambda^2 + \nu^2} \qquad (6\,a)$$

It follows from (6 a) that high spatial frequencies ν are much more attenuated than low ones, or when expressed in terms of wave length that short wavelengths in $H(x)$ are much more attenuated than long wavelengths. Thus the low spatial frequency components of $H(x)$ will be dominating the appearance of the pattern $CM_i(x)$ and high spatial frequency components will just lead to slight ripple like undulations. Nevertheless the input $H(x)$ can

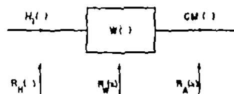

Fig 3 12 Model for the inverse spatial filtering operation. In the ideal situation the input function $H(x)$ can be reconstructed from the output function $CM_i(x)$. In reality 'ripple noise' is present.
$R_A(x)$: ripple noise in the recording system
$R_W(x)$: ripple noise due to inadequate $W(x)$.
$R_H(x)$: ripple noise present in the input function $H(x)$

be recovered unequivocally from $CM_i(x)$ by virtue of the second spatial derivative of $CM_i(x)$ which enhances the ripples of short wavelength, i.e. of high spatial frequency.

However in the real situation the reconstruction of the input $H_i(x)$ from experimental data runs into difficulties because we encounter small irregularities in the output pattern. Let us call these irregularities spatial 'ripple noise' $R(x)$. Thus the experimental CM pattern can be represented as the sum of the ideal pattern $CM_i(x)$ and $R(x)$.

$$CM(x) = CM_i(x) + R(x)$$

When $R(x)$ has wavelengths in the order of magnitude of the short wavelengths in the input pattern it is clearly impossible to obtain an unambiguous reconstruction of the input pattern from the output data. Thus if we want to deduce from experimental CM patterns the corresponding hair-cell output pattern we face the problem of having to identify $R(x)$, or in other words, we must distinguish between ripple noise $R(x)$ and the ideal pattern $CM_i(x)$. This cannot be an easy task, because all we have at hand is $CM(x)$.

The identification of small ripples in experimental CM patterns as ripple noise $R(x)$ would be quite simple provided the ripples occurred at random. Thus if slight undulations in CM patterns are not reproducible within one experimental session and in different experiments we have a certain right to disregard ripples in any one particular CM pattern. By fitting the CM patterns with smooth curves, omitting irregularities of short wavelength we could approximate to $CM_i(x)$ and proceed to calculate $H_i(x)$.

However the ripple patterns shown by our recordings exhibit a high degree of stability and reproducibility. They were found consistently in all preparations. The ripples occurred usually in the regions centered around electrodes 2, 5, 9. This gives an average ripple length of approximately 0.5 mm. It is interesting to note that the ripple length did not change significantly with stimulus frequency. By using

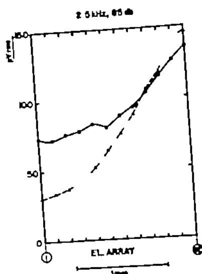

Fig. 3.13 CM amplitude distribution at 2.5 kHz, 85 db, measured before and after overstimulation with 13 kHz, 130 db for 3 min. While the pre-traumatic curve contains small ripples the post-traumatic curve is very smooth. This indicates that the ripples are not dependent on the recording system, i.e. they are not introduced by nonuniformity in electrode channels. $R_S(x)$ can be excluded as a source for ripple noise. ●—● 2.5 kHz CM amplitude pattern before overstimulation with 13 kHz tone, ▲—▲ 2.5 kHz CM amplitude pattern after overstimulation with 13 kHz tone.

equation (1 A) we calculated patterns $H(x)$ which had more than one maximum in the envelope: the ripple pattern seen in the experimental CM patterns appeared strongly enhanced in the deduced $H(x)$.

For the discussion of the question whether the ripples in the experimental CM pattern represent a real phenomenon or just an artefact it is convenient to distinguish three groups of possible sources for the ripples (see Fig. 3.12). $R_H(x)$ denotes the ripple noise occurring in the input signal $H(x)$ itself. $R_W(x)$ designates ripple noise due to the inadequacy of the spatial filter function $W(x)$. $R_S(x)$ designates ripple noise due to imperfection in the recording system, as for instance slight nonuniformity of different electrode channels.

$R_S(x)$: We can rule out $R_S(x)$ on the basis of the following observation. Fig. 3.13 shows the

CM amplitude pattern in response to a stimulus of 2.5 kHz and 85 db SPL. The CM pattern was measured before and after exposing the animal for 3 min to a tone of 13 kHz, and 130 db. The overstimulation with 13 kHz caused impairment of hair-cell activity and consequently there is a marked difference between the two patterns acquired before and after overexposure. As far as the smoothness of the patterns is concerned we can see small irregularities in the pattern measured before overstimulation. In the CM pattern obtained after overstimulation, however, ripples are practically absent. (It may be mentioned here that we always observed relatively smoother CM patterns after subjecting of the guinea pig's ear to excessive stimulation.) The perfectly smooth CM pattern after overstimulation in Fig. 3.13 demonstrates that the electrode array does record patterns without introducing irregularities; thus it is clear that we must seek other reasons for the ripple structure.

$R_B(x)$. A potential source for the ripples in the CM patterns is the curved course of the basilar membrane and the cochlear canals. It is not unlikely that the bending of the cochlear structures has an effect on the potential field in the perilymph. This implies that a straight-lined out core conductor model for the current spread in the basal turn is only valid as a first approximation and that the weighting function $W(x) = \exp(-\lambda |x|)$ is not completely adequate for the description of electrical signal attenuation. If it is true that $W(x)$ does not reflect exactly the spatial properties of the potential spread it is clear that the application of $W(x)$ in the inverse spatial filter operation introduces spatial ripple noise. The original distribution of hair-cell activity can only be correctly reconstructed from CM data provided we know exactly the conditions of potential spread along and across the canals. Since we do not know these conditions exactly—not with the accuracy required for the mathematical deduction of $H(x)$—we cannot estimate the influence of $R_B(x)$ on the resulting $H(x)$, i.e. we cannot estimate the error introduced by the use of a weighting function $W(x)$ which is only a first approximation to the signal spread along the canals.

$R_H(x)$. The ripples observed in the experimental CM patterns could be due to undulations of short wavelength in the hair-cell output pattern; thus they could represent the spatially filtered image of an amplitude pattern modulated on top of the excitation pattern along the membrane. We cannot exclude the possibility that such a modulation pattern could arise from the disturbance of the system by the multi-electrode technique although as was pointed out in Section 2, any significant disturbance of the system seems unlikely. The alternative possibility, namely that the modulation pattern is a genuine property of the system, seems rather odd. However there is some evidence from another source which seems to indicate a certain spatial periodicity structure in the envelope of the excitation pattern. Engström et al. (1966) assessed hair-cell damage along the basilar membrane after exposing animals repeatedly to high intensity noise. Their findings fully agree with the results of other investigators, thus the frequency spectrum of the noise determines the location of maximum damage, the extent and degree of damage depending on SPL. In addition, however, they observed a second feature in the damage pattern:

> The damage often has a kind of maximum center which is bordered by a region of undamaged cells. Beyond this is seen a zone of more pronounced damage on both sides of the center and then a zone of scattered damage. In some cases we have had the impression that the damage had a kind of periodical distribution around a center.

In view of this observation the ripple structure seen in the CM patterns assumes a certain relevance. It is unfortunate that Engström et al. did not mention the wavelength of the spatial periodicity in the damage distribution allowing the comparison with the ripple length of approximately 0.5 mm.

Despite extensive efforts I was not successful in establishing unequivocal criteria for the separation of the ripple noise $R(x)$ from the ideal $CM_i(x)$ in the experimental curves. Without a clear insight into the mechanisms causing the ripples we cannot identify accurately in any one particular CM pattern those features which are due to $R(x)$ and those which represent genuine information about short wavelengths in the hair-cell output pattern. Analytic treatment of the compound experimental CM pattern, with the equation for the inverse spatial filtering, however unduly magnifies the spatial frequency components due to $R(x)$. This clearly indicates the serious limitations of a purely analytical approach in the evaluation of CM data.

The previously outlined, graphical method produced a close approximation $H(x)$ to the hair-cell output pattern along the basilar membrane $H(x)$ was in accordance with data about the mechanical frequency response curves. In the approximative sense the CM patterns fully support $H(x)^*$ yet, in the strict mathematical sense we cannot prove that $H(x)^*$ is the only possible function which corresponds to the measured CM patterns. The question of uniqueness remains unsolved. The inversion of the spatial filter operation gave a neat expression but was not very useful in the treatment of data. By analogy to linear filter theory we can appreciate the difficulties: it cannot be an easy task to reconstruct the input signal from the output signal of a low pass filter in the presence of noise.

C. NONLINEAR STUDIES

The multi-electrode technique is well suited for the study of local changes in the hair-cell output pattern $H(x)$. Such changes influence the whole CM pattern, the influence being strongest in the region of the occurring change and progressively less on either side. We can conveniently express this spatially weighted influence of local changes in $H(x)$ by means of equation (1). Let $CM_B(x)$ be the distribution corresponding to $H_B(x)$:

$$CM_B(x) = \int_{-\infty}^{\infty} H_B(z)\, W(x-z)\, dz$$

By a local change, $\Delta H_{BA}(x)$, in the original hair-cell output distribution $H_B(x)$ we obtain the modified $H\ (x)$

where $\Delta H_{BA}(x) = H_B(x) - H_A(x)$

$H\ (x)$ has a corresponding CM distribution $CM\ (x)$.

$$CM_A(x) = \int_{-\infty}^{\infty} H_A(z)\, W(x-z)\, dz$$

Due to the linearity of the spatial filter operation we can write for the difference between $CM_B(x)$ and $CM_A(x)$:

$$CM_B(x) - CM_A(x) = \Delta CM_{BA}(x)$$

$$\begin{aligned}\Delta CM_{BA}(x) &= \int_{-\infty}^{\infty} H_B(z)\, W(x-z)\, dz - \int_{-\infty}^{\infty} H\ (z)\, W(x-z)\, dz \\ &= \int_{-\infty}^{\infty} (H_B(z) - H_A(z))\, W(x-z)\, dz \\ &= \int_{-\infty}^{\infty} \Delta H_{BA}(z)\, W(x-z)\, dz \\ &= \Delta H_{BA}(x) * W(x) \qquad (1\,D)\end{aligned}$$

Thus the change in the CM pattern $\Delta CM_{BA}(x)$ is the spatially filtered image of $\Delta H_{BA}(x)$. It is essential to realize this property of the spatial filtering process: a local modification of a given hair-cell activity distribution does not produce an equally well localized alteration in the corresponding CM distribution. The effect of a local change in $H(x)$ is distributed along the whole CM pattern according to the attenuation function $W(x)$. Clearly this has an important bearing on the experimental study of localized alterations in the hair-cell output

CM amplitude pattern in response to a stimulus of 2.5 kHz and 85 db SPL. The CM pattern was measured before and after exposing the animal for 3 min to a tone of 13 kHz, and 130 db. The overstimulation with 13 kHz caused impairment of hair-cell activity and consequently there is a marked difference between the two patterns acquired before and after overexposure. As far as the smoothness of the patterns is concerned we can see small irregularities in the pattern measured before overstimulation; in the CM pattern obtained after overstimulation, however, ripples are practically absent. (It may be mentioned here that we always observed relatively smoother CM patterns after subjecting of the guinea pig's ear to excessive stimulation.) The perfectly smooth CM pattern after overstimulation in Fig. 3.13 demonstrates that the electrode array does record patterns without introducing irregularities; thus it is clear that we must seek other reasons for the ripple structure.

$R_B(x)$. A potential source for the ripples in the CM patterns is the curved course of the basilar membrane and the cochlear canals. It is not unlikely that the bending of the cochlear structures has an effect on the potential field in the perilymph. This implies that a straightened out core conductor model for the current spread in the basal turn is only valid as a first approximation and that the weighting function $W(x) = \exp(-\lambda |x|)$ is not completely adequate for the description of electrical signal attenuation. If it is true that $W(x)$ does not reflect exactly the spatial properties of the potential spread it is clear that the application of $W(x)$ in the inverse spatial filter operation introduces spatial ripple noise. The original distribution of hair-cell activity can only be correctly reconstructed from CM data provided we know exactly the conditions of potential spread along and across the canals. Since we do not know these conditions exactly—not with the accuracy required for the mathematical deduction of $H(x)$—we cannot estimate the influence of $R_W(x)$ on the resulting $H(x)$, i.e. we cannot estimate the error introduced by the use of a weighting function $W(x)$ which is only a first approximation to the signal spread along the canals.

$R_H(x)$. The ripples observed in the experimental CM patterns could be due to undulations of short wavelength in the hair-cell output pattern; thus they could represent the spatially filtered image of an amplitude pattern modulated on top of the excitation pattern along the membrane. We cannot exclude the possibility that such a modulation pattern could arise from the disturbance of the system by the multi-electrode technique although, as was pointed out in Section 2, any significant disturbance of the system seems unlikely. The alternative possibility, namely that the modulation pattern is a genuine property of the system, seems rather odd. However there is some evidence from another source which seems to indicate a certain spatial periodicity structure in the envelope of the excitation pattern. Engström et al. (1966) assessed hair cell damage along the basilar membrane after exposing animals repeatedly to high intensity noise. Their findings fully agree with the results of other investigators; thus the frequency spectrum of the noise determines the location of maximum damage, the extent and degree of damage depending on SPL. In addition, however, they observed a second feature in the damage pattern.

> The damage often has a kind of maximum center which is bordered by a region of undamaged cells. Beyond this is seen a zone of more pronounced damage on both sides of the center and then a zone of scattered damage. In some cases we have had the impression that the damage had a kind of periodical distribution around a center.

In view of this observation the ripple structure seen in the CM patterns assumes a certain relevance. It is unfortunate that Engström et al. did not mention the wavelength of the spatial periodicity in the damage distribution allowing the comparison with the ripple length of approximately 0.5 mm.

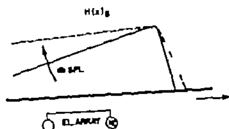

Fig 3.14 Schematic representation of recording situation at 5 kHz. The maximum excitation happens apical to the electrode array The differential growth of $H(x)_s$ in the nonlinear part of the dynamic range is indicated by flattening the basal and apical slopes. Peak-limiting occurs first in the central region of the excitation pattern. Electrode 1 is expected to record relatively more increase in CM amplitude than 12 with increase in SPL.

CM recorded with an electrode situated in the region of maximum displacement. The output of such an electrode is dominated by the contributions from hair-cell generators in this region. Since it is to be expected that saturation of hair-cell outputs with increasing stimulus intensity begins first in the region of maximum displacement it follows that the rate of increase declines much more in this region than in the regions on either side. Out-of phase contributions from the basal and apical parts of the hair-cell output pattern will therefore increase relative to the contributions from the saturated hair-cell generators and a drop in the observed electrode output will result. This rather attractive explanation implies—although not explicitly stated by Whitfield & Ross—that electrodes apical and basal to the considered electrode must continue to record increasing CM because of the continued growth of hair-cell outputs in the apical and basal part of the displacement patterns with increase in sound pressure Our experimental data fully support the hypothesis.

Let us consider the case of $H(x)_f$ that is the hair-cell output distribution at stimulus frequency f In the linear part of the dynamic range $H(x)_f$ increases uniformly with increasing sound pressure and so does the resulting CM(x) (see Fig. 3.10) All hair-cell outputs grow in equal proportion and the shape of $H(x)_f$ remains unaffected. In the nonlinear range characteristic variation of the shape of $H(x)$ must occur due to the growth differential of hair-cell outputs along the basilar membrane In the region of maximum displacement nonlinear limiting of $H(x)_f$ will appear foremost, yet the remaining apical and basal parts of $H(x)_f$ will grow further at unreduced rate with increase in sound pressure. Thus the basal and apical parts of $H(x)$ increase relative to the central part. Such a differential growth of $H(x)_f$ must produce characteristic alterations in the shape of the corresponding CM amplitude and phase pattern The basal and apical parts of $H(x)_f$ will exert increasingly more influence on the CM pattern with increasing SPL. We may expect the following features of CM(x) in the nonlinear part of the dynamic range.

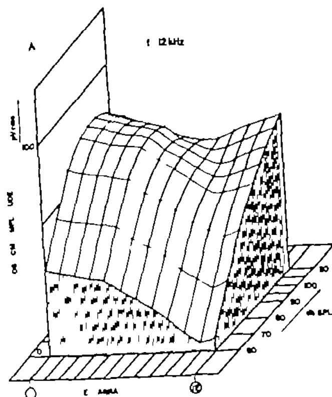
1) The CM in the basal and apical regions of $H(x)_f$ saturates at relatively higher SPLs than the CM in the central region of maximum displacement.

2) The CM in the central region decreases while the CM in the basal and apical regions continues to increase.

3) The tendency of the shape variation of the CM phase pattern indicates the increasing influence of the unsaturated parts of $H(x)_f$ on the CM distribution.

The observable variation of the shape of a CM pattern depends in any one particular case on the position of the electrode array relative to the maximum displacement of the basilar membrane. Fig. 3.14 shows schematically the recording situation at a stimulus frequency of 5 kHz.

The maximum displacement at 5 kHz occurs apical to the electrode array and consequently we observe a CM pattern predominantly influenced by the basal part of $H(x)_5$. We can schematically represent the differential growth of $H(x)_5$ in the nonlinear part of the dynamic range by flattening the basal and apical slopes. Thus with increasing sound pressure electrode 1 will record relatively more increase in CM amplitude than electrode 12. In Fig. 3.15 the



of a given $H(x)$. The information about a local change $\Delta H_{BA}(x)$ is contained in the variation of the *shape* of the *whole* CM pattern and thus concerns both the CM amplitude and the CM phase pattern. Hence for the description of $\Delta H_{BA}(x)$ we require the knowledge of the shape variation of CM(x). Needless to say that the traditional techniques with only a few widely spaced recording points along the cochlea cannot meet this requirement since they do not provide sufficient information about the shape of the CM amplitude and phase pattern in the first place and, of course, even less so about the shape variation of the CM pattern. Although the multi-electrode technique allows the study of CM potentials only over a short length of membrane, nevertheless it provides all information needed for the description of events in this region. The usefulness of the multi-electrode technique in the investigation of local, that is differential changes in hair-cell output is exemplified in the following sections. We have chosen for this study: 1) The differential growth of $H(x)$ in the nonlinear part of the CM intensity function, 2) two-tone interaction, and 3) tonal overstimulation.

In order to facilitate the discussion of the following graphs it is helpful to mention explicitly the dual aspects which will be considered. On the one hand the variations in the shape of CM amplitude and phase patterns indicate the underlying changes in the corresponding hair-cell output pattern. On the other hand the local changes in $H(x)$ which have presumably taken place—in any one specific case—cause a characteristic variation in the shape of the resulting CM pattern; this variation conforms to the concept of spatial filtering.

The CM intensity function

The intensity function, that is the relation between CM amplitude and sound pressure has been studied by many investigators (see for instance Wever 1949, Tasaki et al. 1952, Honrubia & Ward, 1968). It is linear up to about 60 to 70 db SPL; it deviates slightly from linearity between 70 and 90 db SPL and becomes strongly nonlinear beyond 100 db SPL. The saturation shown by the intensity function indicates peak limiting in the potential excursions of hair-cell outputs due to some nonlinear property of the mechano-electric transduction process. Models for the nonlinear behaviour of the CM at high stimulus intensities were suggested by Johnstone & Johnstone (1966) and Engebretson & Eldredge (1968); these models, however, do not provide any explanation for the decrease in the CM at very high intensities. The decline of the CM amplitude at high input levels is a curious feature of the intensity function and it cannot be described by a simple polynomial nonlinearity in the transducer system. Wever (1949) postulated that the drop in the intensity function is the result of the combined effect of two separate mechanisms without, however, clearly specifying these mechanisms. Davis & Eldredge (1959) advanced the hypothesis that longitudinal slippage between the tectorial membrane and the organ of Corti bends—at large sound pressures—the stereocilia of the outer hair cells sideways at right angles to their effective direction of movement. Such a bending of stereocilia, it is argued, could reduce their deflection in the most effective direction and thus cause a drop in hair-cell output. As far as the experimental investigation of such an intricate mechanism is concerned Davis & Eldredge granted that "it is difficult to test or even assess this situation".

Whitfield & Ross (1965) suggested an experimentally testable hypothesis. They proposed phase cancellation between outputs of hair-cell generators as the mechanism responsible for the decrease in CM amplitude at high input levels. In their model the hair-cell output itself is assumed to follow an intensity function with saturation but without decrease at high stimulus intensities. By considering the differences in the rate of increase between hair-cell outputs along the excitation pattern with increase in stimulus intensity they obtained an elegant explanation for the drop in

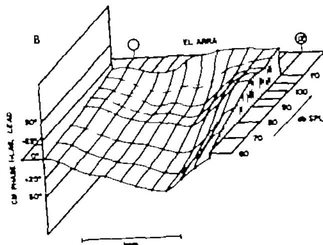


Fig. 3.16 Experimental CM amplitude (A) and phase (B) pattern at 12 kHz as function of SPL. (Data in Figs. 3.16 and 3.15 were obtained in the same guinea pig.)

(A) Note saturation in the basal part of the array: apical CM outputs continue to increase.

(B) At high SPLs the phase values in the apical part of the array dominate the CM phase patterns. This indicates the increasing influence of contributions from the apical part of the hair-cell output distribution on the CM pattern. The contour of 'zero-phase' is drawn into the graph (–). The phase readings are referred to the phase value of 1 at 60 db.

we expect to find an increasing influence of the apical portion of $H(x)$ on the CM pattern recorded with the electrode array. The phase diagram in Fig. 3.16 *B* clearly demonstrates this increasing influence. We observe in this graph a distinct tendency of phase values to shift towards the phases in the apical part of the array: we may say that the apical phase values tend to dominate the shape of the phase pattern with increasing sound pressure.

Two more examples obtained from another guinea pig are shown in Figs. 3.17 and 3.18.

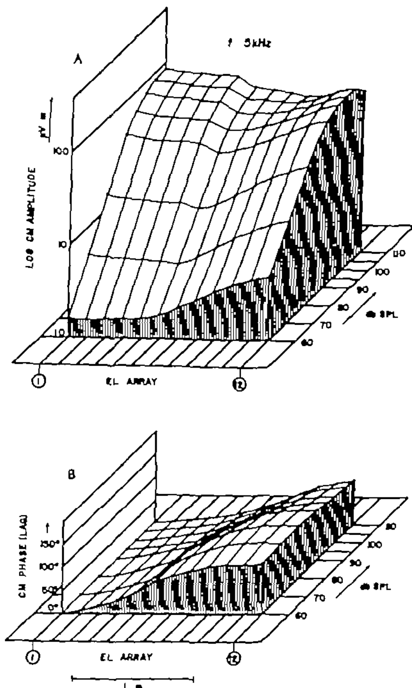

Fig 3.15 Experimental CM amplitude (A) and phase (B) pattern at 5 kHz as a function of SPL.

(A) Note the saturation in the apical part of the array i.e. the part closest to the *maximum displacement at 5 kHz. At* 12 CM amplitude declines while basal electrode outputs continue to increase.

(B) The phase reading are referred to the phase value of 1 at 60 db

experimental CM amplitude and phase patterns at 5 kHz and SPLs from 60 to 110 db are shown It can be seen at once from the 3-dimensional graph that saturation occurs in the apical part of the array that is in the part nearest to the region of maximum displacement It is also interesting to note that the CM amplitude drops at electrode 12 while *for instance at electrode 1 no such drop occurs. Quite the reverse is true in the 12 kHz record shown in Fig. 3 16* (The data in Fig. 3 15 and Fig 3 16 stem from the same animal) Here, electrode 1 records a decrease in CM amplitude, while electrode 12 records continued increase in CM amplitude This is not a surprising situation when we consider the position of the maximum displacement of the basilar membrane at 12 kHz According to Greenwood's formula (*G*) the maximum is located in the region around electrodes 9 and 10 i e within the width of the electrode array Thus in the non-linear part of the dynamic range

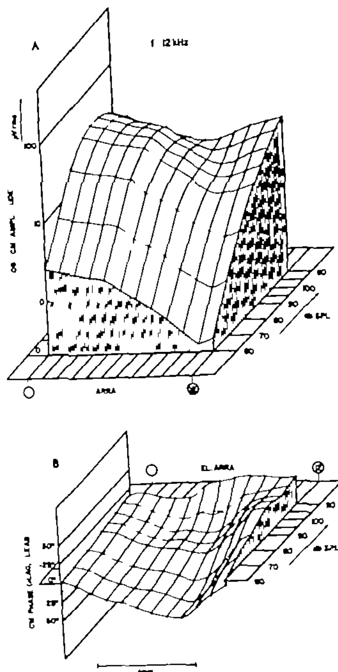

Fig. 3.16 Experimental CM amplitude (A) and phase (B) pattern at 12 kHz as function of SPL. (Data in Figs. 3 16 and 3 15 were obtained in the same guinea pig.)

(A) Note saturation in the basal part of the array apical CM outputs continue to increase.

(B) At high SPLs the phase values in the apical part of the array dominate the CM phase patterns. This indicates the increasing influence of contributions from the apical part of the hair-cell output distribution on the CM pattern. The contour of zero-phase is drawn into the graph (– – –) The phase readings are referred to the phase value of 1 at 60 db.

we expect to find an increasing influence of the apical portion of $H(x)$ on the CM pattern recorded with the electrode array The phase diagram in Fig. 3 16 *B* clearly demonstrates this increasing influence. We observe in this graph a distinct tendency of phase values to shift towards the phases in the apical part of the array we may say that the apical phase values tend to dominate the shape of the phase pattern with increasing sound pressure.

Two more examples obtained from another guinea pig are shown in Figs. 3 17 and 3 18

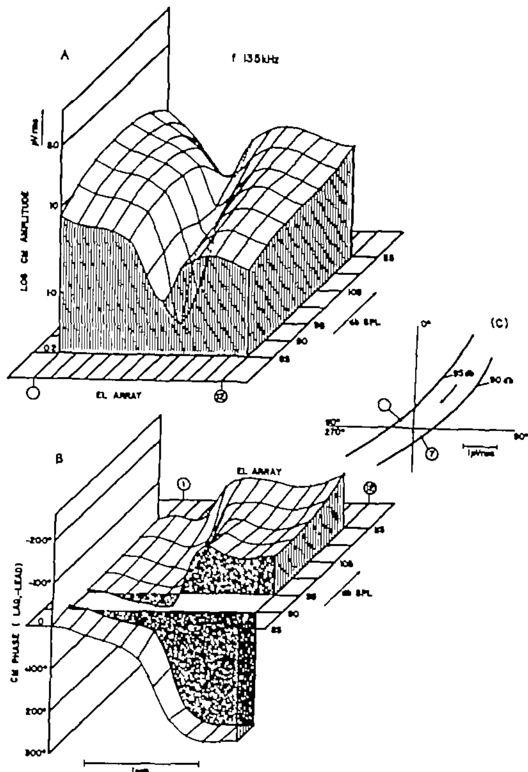

Fig. 3.17. CM amplitude (A) and phase (B) pattern measured at 13.5 kHz as a function of SPL.

(A) Note drop in amplitude in the basal region of the array; the amplitude in the apical region shows continued increase in amplitude.

(B) Notice the growing dominance of apical phase values over phase pattern with increasing SPL. The phase values are referred to that of 1 at 85 db.

(C) Vector representation. Phase reversal occurs between 90 db and 95 db. A short section of the trajectory in the 90 db and 95 db case is shown. The arrow along the two trajectories denotes the apical direction along electrode array. The 90 db trajectory encircles the origin of the vector plane while the 95 db trajectory does not. Output 7 comes very close to the origin. By addition of a small vector with large phase lag to the 90 db trajectory one obtains a trajectory similar to that at 95 db, i.e. with no encirclement of the origin. The additional small vector is thought to represent the relati e increase in the large phase-lag contributions from the apical region of the 13.5 kHz hair-cell output distribution. (Consult Fig. 3.2.D for the ector addition.)

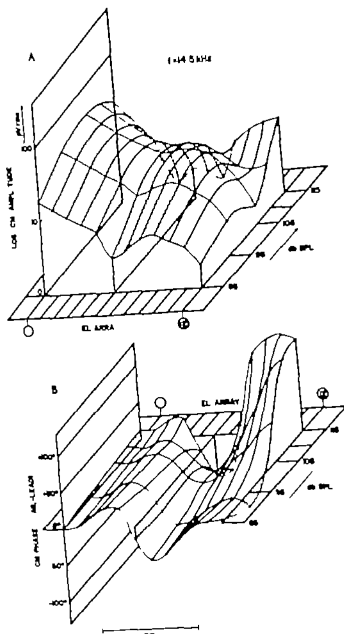

Fig. 3.18 CM amplitude (A) and phase (B) pattern measured at 14.5 kHz as function of SPL. (Figs. 3.17 and 3.18 refer to the same guinea pig.)

(A) Marked increase in CM amplitude in the apical part of the array—the remaining part show marked decrease in amplitude.

(B) Apical phase values clearly dominate CM phase pattern with increase in SPL. The phase values are referred to that of 1 at 85 db.

the stimulus frequency in the two cases was 13.5 kHz and 14.5 kHz respectively. At these frequencies maximum displacement of the basilar membrane occurs in the region around electrodes 8 and 9 and consequently the apical part of $H(x)$ will be dominating the shape variation of the CM distribution along the array with increasing SPL. The 13.5 kHz record in Fig. 3.17 exhibits the characteristic features of this dominating influence in the amplitude as well as the phase patterns. While the basal part of the array shows a drop in CM amplitude the apical part does not. The typical tendency of CM phase values to shift with increasing SPL towards the phase values of the apical part of the array is well shown in the

13.5 kHz phase record. A particularly interesting feature of the 13.5 kHz record is the occurrence of phase reversal between the 90 db and 95 db pattern. At these intensities there is a distinct amplitude minimum at electrode 7. By plotting the data in vector form one obtains trajectories which run very close to the origin; this is indicated in Fig. 3.17 C, where a short section of the trajectory has been drawn for the 90 db and the 95 db pattern. It can be seen that the output of electrode 7 comes very near to the origin of the vector plane. The 90 db trajectory encircles the origin, hence there is progressive phase lag along the electrode array. The 95 db trajectory, however, shows no encirclement and phase reversal within the CM phase pattern must occur. It is apparent that CM patterns with a distinct amplitude minimum are potentially useful in detecting small variations in the shape of the corresponding hair-cell output pattern. A CM amplitude minimum in a case like the one in Fig. 3.17 is the result of mutual, almost total cancellation of contributions from out-of-phase hair-cell generators; in other words at such an amplitude minimum the out-of-phase contributions balance each other. Any slight change in the shape of the hair-cell output distribution will upset the balance and alter the CM pattern in favour of those contributions which showed a relative increase. Thus in the above 13.5 kHz case we would expect a relative increase in the apical part of $H(x)$ with increase in SPL, enhancing the influence of large phase lag contributions on the shape of the CM pattern. We may represent this relative increase by adding a small vector with a large phase lag to all electrode outputs in the 90 db case in which the trajectory encircles the origin. The length of the additional vector diminishes as we proceed towards the basal end of the electrode array. It is obvious that the resulting trajectory will not encircle the origin; hence the resulting 95 db phase pattern will show phase reversal. (The reader may consult Fig. 3.2.D which shows schematically the effect of the above described vector addition.)

The 14.5 kHz record in Fig. 3.18 exhibits once more the characteristic features mentioned in the discussion of the previous diagrams. The apical electrodes of the array record a distinct increase in CM amplitude while the remaining electrode outputs drop drastically with increase in SPL. Concomitant to the increasing amplitude in the apical part of the array there is a clear, growing dominance of apical phase values over the phase pattern.

Two-tone interaction

It is a well known fact that an intense tone decreases the CM amplitude of a simultaneously presented second tone (Wever et al., 1940). It is however a less well known fact that a high frequency tone is more effective in causing a reduction in the CM of an equally intense low frequency tone than the reverse. Although there are several indications to that end in the literature this property of two-tone interaction has never received much attention (see Wever et al., 1940, p. 271, Fig. 4; Nieder & Nieder, 1968 a, 1968 b). Traditionally two-tone interaction studies were carried out with one recording electrode on the round window membrane or with a set of widely spaced electrodes along the cochlear partition. It is the purpose of this section to demonstrate that the multi-electrode technique is very useful for the investigation of this phenomenon because it provides—unlike the traditional techniques—information about the shape variation of a given CM pattern in the presence of a second tone. One would expect that in response to a bitonal stimulus interaction would occur in the region of the basilar membrane where the excitation patterns of the two single stimuli overlap. It is here that hair-cell outputs of one stimulus are modified due to the presence of the other stimulus, provided, that is, that the system is driven in the nonlinear part of the dynamic range. Thus tonal interaction is essentially a local phenomenon and the hair-cell output pattern of the first stimulus is affected only

in those parts where it overlaps with the output pattern of the second stimulus.

In Fig. 3.19.A a typical example of the mutual effect of two tonal stimuli on their respective CM amplitude distributions is given, the SPL of both stimuli was 90 db the fre quencies being 13 kHz and 8 kHz respectively Despite the fact that the CM amplitude of the 13 kHz pattern is much smaller than that of the 8 kHz pattern, especially in the apical part of the array it is the 13 kHz tone which causes a drastic reduction in the 8 kHz pat tern, while the 8 kHz tone has very little effect on the 13 kHz pattern. Thus the higher fre quency stimulus is more effective in influenc ing the CM pattern of the lower frequency stimulus in the basal turn than the reverse. For the interpretation of this observation it would certainly be misleading to judge the magnitude of the local mechanical stimuli activating the hair-cell generators directly on the basis of the CM amplitude at any one elec trode out of the array Since the 13 kHz CM is smaller in amplitude one would have to argue that the locally 'smaller 13 kHz stimulus is more effective in tonal interaction than the locally larger 8 kHz stimulus This, of course, is not the case and Fig. 3.19.A clearly demon strates that the CM amplitude at any one electrode is not a direct measure of the ampli tude of the corresponding local mechanical stimulus applied to the membrane. The CM pattern is the spatially filtered image of the hair-cell output distribution the CM amplitude in the 13 kHz pattern is smaller than that of the 8 kHz pattern due to the shorter wave lengths of the excitation pattern and the consequent stronger phase cancellation effect.

The data in Fig. 3.19.A can be explained by reference to the work of Engebretson & Eldredge (1968). These authors studied the proper ties of an electrical analogue model with peak clipping intended to mimic the nonlinear characteristics of a unit generator along the membrane. A particularly interesting feature of their model was the greater *effectiveness* of a larger stimulus in reducing the response due

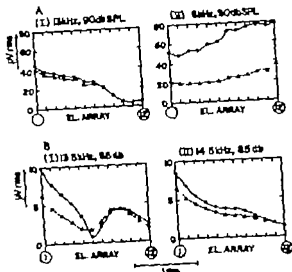

Fig. 3.19 (A) Typical example of mutual influence of two tones on their respective CM amplitude distributions. The 8 kHz tone has very little effect on the 13 kHz CM pattern, the 13 kHz tone, however causes drastic reduction in CM response of the 8 kHz tone. (A I): ●—● 13 kHz (90 db) pattern; ▲—▲, 13 kHz (90 db) pattern in the presence of 8 kHz (90 db). (A II): ●—● 8 kHz (90 db) pattern, ▲—▲ 8 kHz (90 db) pattern in the presence of 13 kHz (90 db).

(B) Typical interaction pattern in the case of two tones with little difference in frequency i.e. nearly 'co-extensive' excitation distributions. (A and B were obtained from different guinea pigs.) The mutual influence of the two tones on their respective CM amplitude patterns is nearly equal. (B.I): ●—● 13.5 kHz (85 db) pattern; ▲—▲ 13.5 kHz (85 db) pattern in the presence of 14.5 (85 db). (B.II): ●—● 14.5 kHz (85 db) pattern; ▲—▲ 14.5 kHz (85 db) pattern in the presence of 13.5 kHz (85 db).

to a weaker stimulus; the weaker stimulus had only very little *effect* on the output of the stronger stimulus. This *feature* applies to the situation in Fig. 3.19.A. According to Greenwood's function (G_1) maximum displacement occurs at 13 kHz in the region around electrodes 8 and 9 maximum displacement of the 8 kHz *excitation* pattern, however occurs apical to the array position. Thus the 13 kHz stimulus is locally (that is in the region of the electrode array) stronger than the 8 kHz *stimulus*. It is therefore not surprising to find a relatively stronger influence of the 13 kHz

tone on the 8 kHz CM pattern than the reverse.

One would predict on the basis of the analogue model that two tones whose excitation patterns overlap each other almost entirely would exert very nearly equal mutual influence on their respective CM patterns. This case is illustrated in the typical example of Fig. 3.19 B. Both stimuli (13.5 kHz and 14.5 kHz) were equally intense (85 db). It can be seen that both CM amplitude patterns are affected to an almost equal degree by tonal interaction.

The examples given clearly indicate that tonal interaction is a local phenomenon depending on the extent to which two interacting excitation patterns overlap. The multi-electrode technique providing information about the spatially graded influence of interacting stimuli may prove useful in the study of this and other related nonlinear phenomena.

Tonal overstimulation

One may speculate that the recording of electrical signals from the cochlea is potentially a more sensitive method of assessing experimentally induced local hair-cell damage than the conventional histological techniques. This could be so because loss of hair-cell activity may precede histologically verifiable damage. In theory there exists the possibility to reconstruct from electrical recordings the extent of activity loss. Let $CM_B(x)$ and $CM_A(x)$ be the CM patterns measured before (B) and after (A) application of a traumatic stimulus S. Imagine that B and A were obtained for the same test stimulus. According to equation (1 D) the difference between the two CM patterns, $\Delta CM_{BA}(x)$ is the spatially filtered image of the difference between the corresponding hair-cell output distributions, $\Delta H_{BA}(x)$:

$$\Delta CM_{BA}(x) = \Delta H_{BA}(x) W * (x) \qquad (1\,D)$$

with the inverse spatial filter operation $\Delta H_{BA}(x)$ can be written in the form

$$\Delta H_{BA}(x) = \frac{\lambda}{2}\Delta CM_{BA}(x) - \frac{1}{2\lambda}\Delta CM''_{BA}(x) \qquad (1\,E)$$

$\Delta H_{BA}(x)$ is the hair-cell activity loss due to the effect of the traumatic stimulus S and theoretically speaking it can be reconstructed according to equation (1 E) provided $\Delta CM_{BA}(x)$ is known from the experiment. However in reality one faces the problem whether the weighting function $W(x)$ was affected by the application of S, i.e. whether the signal conduction properties of the cochlea were altered; for instance one could imagine that the collapse of hair cells changes the conditions for the signal spread along the canals. In cases where S influences the weighting function equation (1 E) is not valid because it requires

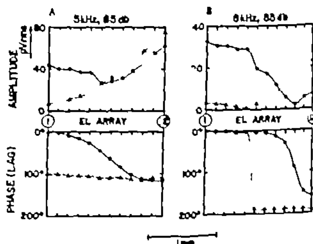

Fig. 3.20. Effect of tonal overstimulation (exposure tone 13 kHz, 130 db, 3 min) on the CM amplitude and phase patterns of two test tones 5 kHz, 85 db (A) and 8 kHz 85 db (B). (A and B obtained in the same guinea pig.) ●—● Pattern before overstimulation with 13 kHz tone. ▲—▲ pattern after overstimulation with 13 kHz tone. The phase values in the post-traumatic situation are referred to that of 1 in the pretraumatic situation.

(A) Relative decrease of amplitude in the basal, relative increase in the apical part of the array. Shift in basal phase values towards apical phase values. This points to the dominant influence of large-phase-lag contributions from unimpaired apical hair-cell generators.

(B) Shape variation similar to that in (A). Note the disappearance of the amplitude minimum at 10 after overstimulation. The persistence of basal phase values indicates residual hair-cell activity in the basal part of the hair-cell output pattern.

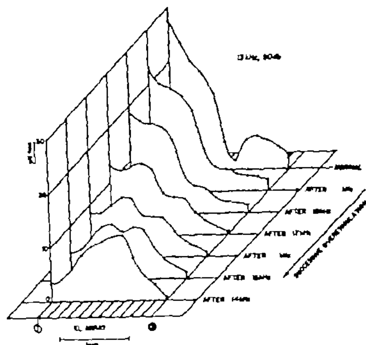

Fig. 3.21 CM amplitude pattern of test tone, 13 kHz, 90 db, shown after successive overstimulation with exposure tones. The pre-traumatic pattern is marked NORMAL. Each exposure tone was applied at 130 db for 3 min. The CM pattern AFTER 21 kHz exposure tone, AFTER 21 20, 19 kHz exposure tones etc. is displayed. Thus AFTER 14 kHz denotes the 13 kHz (90 db) CM pattern obtained after successive overstimulation with 21 20 19 ... 15 14 kHz. Notice the amplitude minimum at 7 in the NORMAL pattern, this minimum disappears upon over stimulation. Note the relative decrease in amplitude *in the basal part of the array* which contrasts well with the relative increase around electrodes 7 8, 9

equal weighting functions for the pre- and post-traumatic situations. Thus for any one traumatic stimulus S it is necessary to establish the constancy of $W(x)$ before equation (1 D) can be applied with confidence. Clearly this can only be achieved by a large series of experiments using graded traumatic stimuli S and complementary histological inspections. Since these investigations were beyond the scope of the present project we did not pursue the matter to the desirable depth. Nevertheless, we did perform some related experiments and the results indicate the suitability of the multi-electrode technique in the study of experimentally induced, local hair-cell activity loss. Moreover the results fully conform to the concept of spatial filtering and this is the main reason why some examples are given here.

Fig. 3.20 displays the results obtained in an experiment concerned with tonal overstimulation The CM amplitude and phase patterns of a 5 kHz and 8 kHz test tone (85 db) were measured before and after overstimulating the guinea pig's ear with a 13 kHz tone of 130 db for 3 min. The 13 kHz exposure tone causes maximum disturbance (according to Greenwood's formula G_1) in the region around electrodes 8 and 9 and it is probably correct to assume that hair-cell activity loss results especially in this and the more basal region due to the flat basal slope of the excitation pattern. Thus, as far as the 5 kHz and 8 kHz test excitation patterns are concerned, we would expect a reduction in hair-cell output in the basal parts of their hair-cell output patterns. This expectation is confirmed by the results in Fig. 3.20. The 5 kHz pattern shows a marked decrease in CM amplitude in the basal part of the array while the amplitude shows a relative increase in the apical part. It is interesting to note that in the 5 kHz phase pattern phase values shift towards the apical phases indicating the dominating influence of large-phase lag contributions from unimpaired hair-cell generators. Essentially similar shape variation of the CM pattern occurs in the 8 kHz case. However the persistence of basal phase values demonstrates residual hair-cell activity in the basal region of the hair-cell output pattern. The 8 kHz CM amplitude pattern lends strong

tone on the 8 kHz CM pattern than the reverse.

One would predict on the basis of the analogue model that two tones whose excitation patterns overlap each other almost entirely would exert very nearly equal mutual influence on their respective CM patterns. This case is illustrated in the typical example of Fig. 3.19 B. Both stimuli (13.5 kHz and 14.5 kHz) were equally intense (85 db). It can be seen that both CM amplitude patterns are affected to an almost equal degree by tonal interaction.

The examples given clearly indicate that tonal interaction is a local phenomenon depending on the extent to which two interacting excitation patterns overlap. The multi-electrode technique providing information about the spatially graded influence of interacting stimuli may prove useful in the study of this and other related nonlinear phenomena.

Tonal overstimulation

One may speculate that the recording of electrical signals from the cochlea is potentially a more sensitive method of assessing experimentally induced local hair-cell damage than the conventional histological techniques. This could be so because loss of hair-cell activity may precede histologically verifiable damage. In theory there exists the possibility to reconstruct from electrical recordings the extent of activity loss. Let $CM_B(x)$ and $CM_A(x)$ be the CM patterns measured before (B) and after (A) application of a traumatic stimulus S. Imagine that B and A were obtained for the same test stimulus. According to equation (1 D) the difference between the two CM patterns, $\Delta CM_{BA}(x)$, is the spatially filtered image of the difference between the corresponding hair-cell output distributions, $\Delta H_{BA}(x)$:

$$\Delta CM_{BA}(x) = \Delta H_{BA}(x) W * (x) \qquad (1\,D)$$

with the inverse spatial filter operation $\Delta H_{BA}(x)$ can be written in the form.

$$\Delta H_{BA}(x) = \frac{\lambda}{2}\Delta CM_{BA}(x) - \frac{1}{2\lambda}\Delta CM_{BA}(x) \qquad (1\,E)$$

$\Delta H_{BA}(x)$ is the hair-cell activity loss due to the effect of the traumatic stimulus S and theoretically speaking it can be reconstructed according to equation (1 E) provided $\Delta CM_{BA}(x)$ is known from the experiment. However in reality one faces the problem whether the weighting function $W(x)$ was affected by the application of S, i.e. whether the signal conduction properties of the cochlea were altered, for instance one could imagine that the collapse of hair cells changes the conditions for the signal spread along the canals. In cases where S influences the weighting function equation (1 E) is not valid because it requires

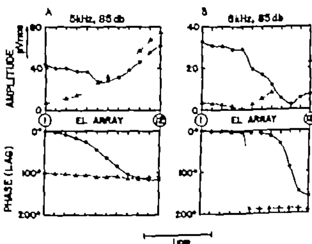

Fig. 3.20. Effect of tonal overstimulation (exposure tone 13 kHz, 130 db, 3 min) on the CM amplitude and phase patterns of two test tones 5 kHz, 85 db (A) and 8 kHz, 85 db (B). (A and B obtained in the same guinea pig.) ●—● Pattern before overstimulation with 13 kHz tone. ▲—▲ pattern after overstimulation with 13 kHz tone. The phase values in the post-traumatic situation are referred to that of 1 in the pretraumatic situation.

(B) Shape variation similar to that in (A). Note the disappearance of the amplitude minimum at 10 after overstimulation. The persistence of basal phase values indicates residual hair-cell activity in the basal part of the hair-cell output pattern.

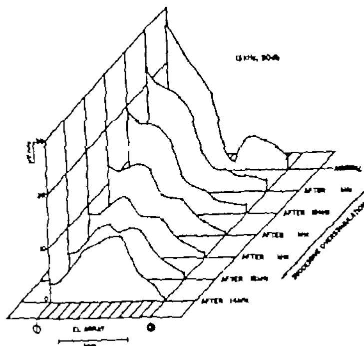

Fig. 3.21 CM amplitude pattern of test tone, 13 kHz, 90 db, shown after successive overstimulation with exposure tones. The pre-traumatic pattern is marked 'NORMAL'. Each exposure tone was applied at 130 db for 3 min. The CM pattern AFTER 21 kHz exposure tone, AFTER 21 20 19 kHz exposure tones also is displayed. Thus 'AFTER 14 kHz' denotes the 13 kHz (90 db) CM pattern obtained after successive overstimulation with 21 20, 19 15 14 kHz. Notice the amplitude minimum at 7 in the 'NORMAL' pattern, this minimum disappears upon over stimulation. Note the relative decrease in amplitude in the basal part of the array which contrasts well with the relative increase around electrodes 7 8, 9

equal weighting functions for the pre- and post traumatic situations. Thus for any one traumatic stimulus S it is necessary to establish *the constancy of $W(x)$ before equation* (1 D) can be applied with confidence. Clearly this can only be achieved by a large series of experiments using graded traumatic stimuli S and complementary histological inspections. Since these investigations were beyond the scope of the present project we did not pursue the matter to the desirable depth. Nevertheless, we did perform some related experiments and the results indicate the suitability of the multielectrode technique in the study of experimentally induced, local hair-cell activity loss. Moreover the results fully conform to the concept of spatial filtering and this is the main reason why some examples are given here.

Fig. 3.20 displays the results obtained in an experiment concerned with tonal overstimulation. The CM amplitude and phase patterns of a 5 kHz and 8 kHz test tone (85 db) were measured before and after overstimulating the guinea pig's ear with a 13 kHz tone of 130 db for 3 min. The 13 kHz exposure tone causes maximum disturbance (according to Greenwood's formula G_1) in the region around electrodes 8 and 9 and it is probably correct to assume that hair-cell activity loss results especially in this and the more basal region due to the flat basal slope of the excitation pattern. Thus, as far as the 5 kHz and 8 kHz test excitation patterns are concerned, we would expect a reduction in hair-cell output in the basal parts of their hair-cell *output patterns*. This expectation is confirmed by the results in Fig. 3.20 The 5 kHz pattern shows a marked decrease in CM amplitude in the basal part of the array while the amplitude shows a relative increase in the apical part. It is interesting to note that in the 5 kHz phase pattern phase values shift towards the apical phases indicating the dominating influence of large-phase-lag contributions from unimpaired hair-cell generators. Essentially similar shape variation of the CM pattern occurs in the 8 kHz case. However the persistence of basal phase values *demonstrates residual hair-cell* activity in the basal region of the hair-cell output pattern. The 8 kHz CM amplitude pattern lends strong

tone on the 8 kHz CM pattern than the reverse.

One would predict on the basis of the analogue model that two tones whose excitation patterns overlap each other almost entirely would exert very nearly equal mutual influence on their respective CM patterns. This case is illustrated in the typical example of Fig. 3.19 B. Both stimuli (13.5 kHz and 14.5 kHz) were equally intense (85 db). It can be seen that both CM amplitude patterns are affected to an almost equal degree by tonal interaction.

The examples given clearly indicate that tonal interaction is a local phenomenon, depending on the extent to which two interacting excitation patterns overlap. The multi-electrode technique providing information about the spatially graded influence of interacting stimuli may prove useful in the study of this and other related nonlinear phenomena.

Tonal overstimulation

One may speculate that the recording of electrical signals from the cochlea is potentially a more sensitive method of assessing experimentally induced local hair-cell damage than the conventional histological techniques. This could be so because loss of hair-cell activity may precede histologically verifiable damage. In theory there exists the possibility to reconstruct from electrical recordings the extent of activity loss. Let $CM_B(x)$ and $CM_A(x)$ be the CM patterns measured before (B) and after (A) application of a traumatic stimulus S. Imagine that B and A were obtained for the same test stimulus. According to equation (1 D) the difference between the two CM patterns, $\Delta CM_{BA}(x)$ is the spatially filtered image of the difference between the corresponding hair-cell output distributions, $\Delta H_{BA}(x)$

$$\Delta CM_{BA}(x) = \Delta H_{BA}(x) W * (x) \qquad (1\,D)$$

with the inverse spatial filter operation $\Delta H_{BA}(x)$ can be written in the form.

$$\Delta H_{BA}(x) = \frac{\lambda}{2}\Delta CM_{BA}(x) - \frac{1}{2\lambda}\Delta CM_{BA}(x) \qquad (1\,E)$$

$\Delta H_{BA}(x)$ is the hair-cell activity loss due to the effect of the traumatic stimulus S and theoretically speaking it can be reconstructed according to equation (1 E) provided $\Delta CM_{BA}(x)$ is known from the experiment. However in reality one faces the problem whether the weighting function $W(x)$ was affected by the application of S, i.e. whether the signal conduction properties of the cochlea were altered, for instance one could imagine that the collapse of hair cells changes the conditions for the signal spread along the canals. In cases where S influences the weighting function equation (1 E) is not valid because it requires

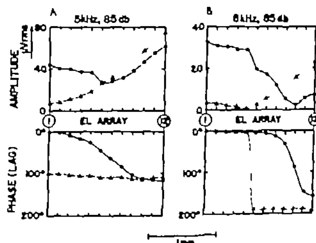

Fig. 3.20. Effect of tonal overstimulation (exposure tone 13 kHz, 130 db, 3 min) on the CM amplitude and phase patterns of two test tones 5 kHz, 85 db (A) and 8 kHz, 85 db (B). (A and B obtained in the same guinea pig.) ●—● Pattern before overstimulation with 13 kHz tone. ▲—▲ pattern after overstimulation with 13 kHz tone. The phase values in the post traumatic situation are referred to that of 1 in the pretraumatic situation.

(A) Relative decrease of amplitude in the basal, relative increase in the apical part of the array. Shift in basal phase values towards apical phase values. This points to the dominant influence of large-phase-lag contributions from unimpaired apical hair-cell generators.

(B) Shape variation similar to that in (A). Note the disappearance of the amplitude minimum at 10 after overstimulation. The persistence of basal phase values indicates residual hair-cell activity in the basal part of the hair-cell output pattern.

Discussion

It was shown that the spatial filter hypothesis adequately describes the relationship between the hair-cell potential distribution and the CM distribution in the cochlear canals. All salient features of experimental CM patterns measured with the multi-electrode array were found to be explicable on the basis of the spatially filtered excitation pattern along the membrane. Our experimental data provide evidence for an electrical excitation pattern $H(x)^*$ whose shape is in agreement with recent measurements of the mechanical behaviour of the basilar membrane in the high frequency region. The shape of $H(x)^*$ suggests a frequency response curve with a high frequency slope of approximately 110 db per octave and a low frequency slope of approximately 10 db per octave. This compares favourably with the results obtained with the Mössbauer technique at an SPL of 90 db. In addition our electrical data complement mechanical measurements in that they provide evidence for the tuning of the membrane at stimulus intensities lower than 90 db where mechanical data are not available. The insignificant shape variation of the CM pattern up to an SPL of 80 to 90 db indicates the uniformity of the mechanical tuning characteristics over this part of the dynamic range.

Von Békésy's studies in the more apical region of the basilar membrane yielded response curves with high frequency slopes distinctly flatter than the ones suggested by the response curves obtained in the basal part of the membrane. However, von Békésy (1960 a, p. 504) noticed in his records the tendency for a greater sharpness with increasing best frequency of the response curves. Given a systematic tendency for greater sharpness, a 'progression in tuning' (Johnstone 1969) from apex to base along the membrane, especially with respect to the high frequency slope, the discrepancy between the recent basal data and von Békésy's more apical data could be resolved. At the present it is impossible to decide this point because direct observation from the intermediate frequency region is lacking and thus a 'progression in tuning' is not substantiated experimentally. One may question whether a progression in tuning would explain the discrepancy between the results completely; it could well be that the different techniques used account to some extent for the difference between the data. Rhode & Geisler (1969) measured high frequency slopes of 90–150 db per octave with the Mössbauer technique in the squirrel monkey; they obtained their results in the 6 to 9 kHz region of the basilar membrane. Von Békésy performed his optical studies up to frequencies of 4 kHz but never did he report of slope values in this order of magnitude. Unfortunately direct comparison is impossible because von Békésy's results do not refer to the squirrel monkey; thus species differences may partly account for differing results. Nevertheless it seems improbable that progression in tuning is the only satisfactory explanation and the techniques employed may be at least partly responsible for the discrepancy between results. The greater resolution of the Mössbauer technique allows the study to be carried out at the moderate SPL of 90 db. Von Békésy worked on post-mortem preparations at probably much higher sound pressures. It is not unlikely that the steep frequency slope is particularly sensitive to slight post-mortem deterioration of inner ear tissues. One could also suspect that the mechanical frequency response curves change shape when sound pressure increases beyond 90 db. However the latter argument does not seem to apply since von Békésy reported linearity of the mechanical vibrations up to SPLs of 130 to 140 db.

support for the spatial filter hypothesis. In the pretraumatic situation electrode 10 records a distinct amplitude minimum in the post traumatic situation however this minimum is lost and apical electrodes show a relative increase in amplitude. This implies, of course, that the pretraumatic amplitude minimum is the result of phase cancellation between contributions from out-of-phase hair-cell generators—it certainly does not indicate a local amplitude minimum in the corresponding hair-cell output pattern. Overstimulation with 13 kHz causes a relative decrease of basal contributions and consequently apical contributions dominate the shape of the 8 kHz CM pattern It is obvious that consideration of the incremental change in the output of any one electrode from the array does not give anything but a very crude idea of events happening in tonal overstimulation It is the shape variation of the CM patterns $\Delta CM_{BA}(x)$ which contains the information about the underlying spatially graded reduction in hair-cell activity $\Delta H_{BA}(x)$

Another example is given in Fig 3.21 Here the test tone had a frequency of 13 kHz and an SPL of 90 db The pretraumatic 13 kHz CM pattern is marked NORMAL in the diagram. In the normal CM amplitude pattern we observe a distinct amplitude minimum at electrode 7 The remaining amplitude patterns were obtained for the same test stimulus (13 kHz, 90 db) the progressive shape variation being due to successive overstimulation of the guinea pig's ear with a series of exposure tones. In 1 kHz-steps the frequency of the exposure tone was changed from 21 kHz to 14 kHz. Each exposure tone was presented for 3 min at an intensity of 130 db The 13 kHz test pattern was measured after each presentation and in Fig. 3.21 some of the test patterns obtained are shown (The marking AFTER 14 kHz means: 13 kHz pattern after successive overstimulation with 21 20, 19 18 15 14 kHz) As the frequency of the exposure tone is decreased one would predict a progressive reduction of hair-cell outputs of the 13 kHz pattern moreover one would expect this reduction to be most prominent in the basal part of the 13 kHz hair cell output pattern Thus with successive overstimulation contributions from the basal part of the hair-cell output distribution decrease relative to the contributions from the central and apical part According to Greenwood's function (G_1) maximum displacement occurs at 13 kHz in the region around electrodes 8 and 9 Hence we expect to find a relative increase in CM amplitude in this region and a relative decrease in the more basal region of the array This tendency is well shown by the systematic shape variation of the 13 kHz CM pattern with successive overstimulation. The amplitude minimum in the normal CM pattern is definitely due to phase-cancellation it disappears when the balance of out-of phase contributions is altered by overstimulation

A particularly interesting, though puzzling feature of Fig. 3 21 is the smooth ripple pattern on top of the CM amplitude distributions. This ripple pattern certainly has not a sporadic character and one would hesitate to classify it as meaningless ripple noise However what it means is impossible to decide on the basis of CM recordings alone

ings in the cochlear walls would interfere with the steep resonance properties of the inner ear it would be possible to disqualify me chano-electric data entirely and the only acceptable data left would be those from primary nerve fibres. Such a situation, however does not appear to exist. The fact that the Mössbauer technique and the multi-electrode technique—both of which require the exposure of the basal scala tympani—do suggest high frequency slopes in the order of 100 db per octave or more is a clear indication that the 'steepness' of the tuning characteristics is retained despite openings. The decisive experiment, however was done by Evans (1970 *b*) He monitored tuning curves from primary neurones with high characteristic frequency before and after exposure of the basal scala tympani in the guinea pig. He found no change in the neural tuning curves after exposing scala tympani. This is convincing evidence for the negligible influence of openings in the cochlear wall on the tuning properties of the inner ear

At the present it seems necessary to postulate a sharpening mechanism intervening between the mechano-electric input of the cochlear transducer and the neural output. Such a sharpening mechanism will be operating mainly as regards the low frequency slope of the neural tuning curves. Johnstone (1969) suggested slope detection as such a possible mechanism. According to his view it is the steep apical slope of the mechanical excitation pattern with the associated large phase gradient which could constitute the adequate stimulus for nerve excitation. Although a slope detector mechanism—that is a detector for the first spatial derivative of the excitation pattern—could be the answer to the problem it nevertheless remains an open question whether such a mode of operation would be satisfactory as other functions of the peripheral transduction are concerned. Taking the first spatial derivative of a given excitation pattern means rarefying the energy mechanically available—an operation inherently unlikely when considering the minute amount of acoustic energy which suffices to produce auditory sensation at threshold. The fibres of the external spiral bundle with their multiple innervation of hair cells appear to be well suited for spatial summation, that is spatial integration, rather than spatial differentiation.

In the search for mechanisms which could be responsible for the symmetrical tuning of auditory nerve fibres one thinks immediately of lateral inhibition as a means for contrast enhancement. Although the efferent fibres of the olivo-cochlear bundle may 'take part in some kind of frequency discrimination (Fex, 1965) it seems improbable that these fibres contribute substantially to the narrow tuning of primary neurones. First of all the total number of efferent fibres is only about 500 and this excludes the necessary resolution required in cochlear sharpening. Second the latency of olivo-cochlear fibres seems prohibitively long for direct participation of this fibre group in shaping the tuning curves of primary fibres. The alternative possibility of local neural loops inside the organ of Corti allowing the direct interaction of signals from different fibres can neither be accepted nor rejected on experimental grounds, it remains at present purely speculative. When speculating about possible neural mechanisms one has to take into consideration the limitations of the temporal capacity of neural systems imposed by the relatively long time constants of synaptic junctions. This is one of the reasons why models based on interaction of signals via electrotonic spread (Huggins, 1953) appear to be particularly attractive.

In view of the enormous technical difficulties of any conceivable direct experimental study of a sharpening mechanism it is probably wise to adopt a somewhat reluctant attitude towards the acceptance of the flat low frequency slope of mechanical tuning curves, the slope which of course calls for such a sharpening mechanism. Could it not be that the basilar membrane is sharply tuned, that it is a juxtaposition of individual resonator elements; could it not be that there is little damp-

It would be interesting to know whether the size of the Mössbauer probe influences the results, especially the value for the steep high frequency slope. There could well be a maximum slope value recordable with a Mössbauer source of a given size in other words it needs to be clarified whether the size of the Mössbauer source imposes certain limitations on the maximum slope values obtainable. Furthermore the slight deviation of the results measured with the Mössbauer technique from Greenwood's *function* (G_1) for the locus of maximum displacement seems to indicate that the Mössbauer probe loads the vibrating tissues thereby reducing their best frequencies slightly to lower values. It appears that a series of experiments is called for with Mössbauer probes of different sizes. Such experiments could furnish the criteria for the assessment of the limitations of the data measured with the Mössbauer technique.

Likewise objections may be raised as regards the high frequency slope value of 110 db per octave suggested by our function "$H(x)$". It must be remembered that "$H(x)$" is the result of a fitting procedure: we assumed hypothetical functions $H(x)$ and we studied the fit between the corresponding hypothetical CM distribution and our experimental CM patterns. $H(x)$ comprises an amplitude and a phase function and it is the combination of these two functions which is responsible for the resulting shape of the corresponding theoretical CM distribution. Thus, in theory slight modifications of the envelope (amplitude) function of "$H(x)$" can be compensated by modifications of the phase function of "$H(x)$" and the resulting CM distribution may appear unchanged. It is therefore obvious that the value of 110 db per octave indicates only the order of magnitude of the high frequency slope—it is in the strict mathematical sense not binding. Theoretically speaking functions $H(x)$ other than the one ("$H(x)$") arrived at by our graphical fitting procedure, could exist, whose spatially filtered image could conform to experimental CM patterns. In the attempt to establish the unique hair-cell *output function* we inverted the spatial filter operation. This inversion, however *raised* additional problems because it exposed the strong influence of spatial ripple noise on the direct analytical deduction of $H(x)$ *from* experimental CM patterns. Although "$H(x)$" is in accordance with mechanical data and therefore *most probably* a correct description of the excitation pattern along the membrane we could not *prove* in this study that it is the *only possible* description satisfying our CM data. Hence the question of uniqueness is *left* unsolved.

The study of the excitation pattern along the membrane via the CM potential distribution along the cochlear ducts is basically an indirect method. The CM pattern is the spatially filtered image, the smeared out version of the electrical excitation pattern. In any case a deductive step is necessary for the recovery of the original excitation pattern from the experimentally accessible CM distribution. The fact that it is an indirect method is accentuated by the problem of spatial ripple noise. The smooth ripple pattern consistently seen in experimental CM distributions hinders the direct deduction of $H(x)$ from CM data and the question of the origin of the ripple structure is raised. This circumstance exposes the shortcomings of the electrical method in the exploration of the excitation pattern.

The major question raised by the studies of the mechano-electric input of the cochlear transducer is not so much concerned with the high frequency slope of the response curves, it is rather that of the flat low frequency slope. The asymmetric shape of the mechanical tuning curves which according to our data seems to apply also at SPLs lower than 90 db is at complete variance with the more nearly symmetric shape of tuning curves from first order neurones at low SPLs. There is no way out from this discrepancy via the route suggested recently by Huxley (1969). Huxley doubted the reliability of results obtained from inner ears which had their canal walls opened for experimental access. If it was true that open

ings in the cochlear walls would interfere with the steep 'resonance properties' of the inner ear it would be possible to disqualify mechano-electric data entirely and the only acceptable data left would be those from primary nerve fibres. Such a situation, however does not appear to exist. *The fact that the Mössbauer technique and the multi-electrode technique*—both of which require the exposure *of the basal scala tympani*—do suggest high *frequency slopes* in the order of 100 db per octave or more is a clear indication that the 'steepness' of the tuning characteristics is retained despite openings. The decisive experiment, however was done by Evans (1970 *b*). He monitored tuning curves from primary neurones with high characteristic frequency before and after exposure of the basal scala tympani in the guinea pig. *He found no change* in the neural tuning curves after exposing scala tympani. This is convincing evidence for the negligible influence of openings in the cochlear wall on the tuning properties of the inner ear.

At the present it seems necessary to postulate a sharpening mechanism intervening between the mechano-electric input of the cochlear transducer and the neural output. Such a sharpening mechanism will be operating mainly as regards the low frequency slope of the neural tuning curves. Johnstone (1969) suggested slope detection as such a possible mechanism. *According to his view it is the steep apical slope of the mechanical excitation pattern* with the associated large phase gradient which could constitute the adequate stimulus for nerve excitation. Although a slope detector mechanism—that is a detector for the first spatial derivative of the excitation pattern—could be the answer to the problem it nevertheless remains an open question whether such a *mode of operation* would be satisfactory as other *functions of the* peripheral transduction are concerned. Taking the first spatial derivative of a given excitation pattern means rarefying the energy mechanically available—an operation inherently unlikely when considering the minute amount of acoustic energy which suffices to produce auditory sensation at threshold. The fibres of the external spiral *bundle with their multiple innervation* of hair *cells appear to be well suited for spatial* summation, that is spatial integration, rather than spatial differentiation.

In the search for mechanisms which could be responsible for the symmetrical tuning of auditory nerve fibres one thinks immediately of lateral inhibition as a means for contrast enhancement. Although the efferent fibres of the olivo-cochlear bundle may 'take part in some kind of frequency discrimination' (Fex, 1965) it seems improbable that these fibres contribute substantially to the narrow tuning of primary neurones. First of all the total number of efferent fibres is only about 500 and this excludes the necessary resolution required in cochlear sharpening. *Second the latency of olivo-cochlear fibres seems prohibitively long for direct participation of this fibre group in shaping the tuning curves of primary* fibres. The alternative possibility of local neural loops inside the organ of Corti allowing the direct interaction of signals from different fibres can neither be accepted nor rejected on experimental grounds, it remains at present purely speculative. When speculating about possible neural mechanisms one has to take into consideration the limitations of the temporal capacity of neural systems imposed by the relatively long time constants of synaptic junctions. This is one of the reasons why models based on *interaction of signals* via electrotonic spread (Huggins, 1953) appear to be particularly attractive.

In view of the enormous technical difficulties of any conceivable direct experimental study of a 'sharpening mechanism' it is probably wise to adopt a somewhat reluctant attitude towards the acceptance of the flat low frequency slope of mechanical tuning curves, the slope which of course calls for such a sharpening mechanism. Could it not be that the basilar membrane is sharply tuned, that it is a juxtaposition of individual resonator elements could it not be that there is little damp-

It would be interesting to know whether the size of the Mössbauer probe influences the results, especially the value for the steep high frequency slope. There could well be a maximum slope value recordable with a Mössbauer source of a given size In other words it needs to be clarified whether the size of the Mössbauer source imposes certain limitations on the maximum slope values obtainable Furthermore the slight deviation of the results measured with the Mössbauer technique from Greenwood's function (G_1) for the locus of maximum displacement seems to indicate that the Mössbauer probe loads the vibrating tissues thereby reducing their best frequencies slightly to lower values. It appears that a series of experiments is called for with Mössbauer probes of *different sizes*. Such experiments could furnish the criteria for the assessment of the limitations of the data measured with the Mössbauer technique

Likewise objections may be raised as regards the high frequency slope value of 110 db per octave suggested by our function "$H(x)$" It must be remembered that "$H(x)$" is the result of a *fitting* procedure we assumed hypothetical functions $H(x)$ and we studied the fit between the corresponding hypothetical CM distribution and our experimental CM patterns. $H(x)$ comprises an amplitude and a phase function and it is the combination of these two functions which is responsible for the resulting shape of the corresponding theoretical CM distribution Thus, in theory slight modifications of the envelope (amplitude) function of "$H(x)$" can be compensated by modifications of the phase function of "$H(x)$" and the resulting CM distribution may appear unchanged It is therefore obvious that the value of 110 db per octave indicates only the order of magnitude of the high frequency slope—it is in the strict mathematical sense not binding Theoretically speaking, functions $H(x)$ other than the one ("$H(x)$") arrived at by our graphical fitting procedure could exist whose spatially filtered image could conform to experimental CM patterns. Could it not be that the basilar membrane is sharply tuned, that it is a juxtaposition of individual resonator elements, could it not be that there is little damp-

ing in the mechanical transducer? Pumphrey & Gold (1948) (Gold & Pumphrey 1947/48) felt that they had convincing, unambiguous psychoacoustic evidence for the 'resonance hypothesis. In their experiment listeners were asked to distinguish between two series of tone pulses. Each pulse consisted of n periods of a 5 kHz tone the silent interval between pulses measured m periods of the 5 kHz tone Let us call a tone pulse which begins with a positive half wave A and that with a negative half wave B Distinction had to be made between the series AAA and the series ABA. The Fourier spectra of the two series are different, they become more and more similar with increasing $(m+n)$ Pumphrey & Gold found that listeners were perfectly capable to distinguish the two series provided the silent interval between pulses was less than $m=30$ periods. For m greater than 30 discriminability became progressively worse and ultimately faded away completely Pumphrey & Gold based their interpretation of the experiment on the temporal aspects of the stimulus signals rather than the difference in the frequency spectra Since the only difference between tone pulses A and B is a 180 phase shift they argued that some kind of phase memory' must exist in the mechanical transducer For ABA to be distinguishable from AAA they reasoned the mechanics of the ear must allow the interaction between a preceding pulse A with the following pulse B or A respectively This implied very little mechanical damping so that the long lasting afteroscillations from the previous pulse could interact with the negative or positive going onset of the following pulse Since discrimination is possible for silent intervals with m up to 30 Pumphrey & Gold concluded that the basilar membrane is extremely lightly damped or what is equivalent that it is extremely sharply tuned The argument would certainly be valid if as Pumphrey & Gold have implicitly assumed the mechanical interaction had to take place in a 5 kHz resonator' This assumption however is false The inner ear is a distributed system not just one single resonator The afteroscillations of a preceding pulse need not interact with the following pulse at one point along the membrane; discrimination seems possible as long as offset transients of the preceding pulse are present on the membrane at the onset of the following pulse Surprisingly it has been constantly overlooked in the past (von Békésy & Rosenblith, 1951 Huxley 1969) that the experimental finding of Pumphrey & Gold is in perfect agreement with von Békésy's direct observations of the basilar membrane vibration which revealed strong damping. According to von Békésy s measurement in the human cochlea a transient disturbance takes about 5 msec to travel from base to apex. However $m=30$ periods of a 5 kHz tone equate to $30\times0.2=$ 6 msec this is the duration of the silent interval between successive tonal pulses for which discriminability starts to deteriorate. Thus it seems that the strongly damped basilar membrane is able to provide the spatial cues for the discrimination required in the experiment of Pumphrey & Gold. It certainly does not follow that this experiment constitutes a valid proof that the resonance hypothesis is true

The apparent necessity to postulate a 'sharpening mechanism must provoke the study of the transduction process itself a study which is essential for the elucidation of the causal chain of linear and nonlinear events leading from mechanical displacement to production of neural spikes. In this investigation we used the electrical potential in the cochlea as an index of mechanical excitation without touching the question of the rule of the potential in eliciting neural impulses. As regards this question opinions vary widely Tasaki (1957) suggested 'that the generation of microphonics appears to be an essential intermediate step intervening between the mechanical motion and initiation of nerve impulses On the other hand Dallos (1969 b) felt that CM potentials might not necessarily form an essential link in the peripheral transduction chain Clearly there seems to be no escape from looking at the transduction itself

Summary

The multi-electrode technique was developed for the study of the potential distribution in the basal 1/2 turn of scala tympani along the basilar membrane in the guinea pig's cochlea.

The salient features of the CM distributions in response to sinusoidal stimuli were found to be consistent with the concept of spatial filtering. According to this concept the CM distribution has to be considered as the spatially filtered image of the electrical activity along the organ of Corti. Various hypothetical activity patterns were tested by comparing their corresponding theoretical CM patterns with experimental CM data. The best fitting activity pattern was compatible with recent observations of the mechanical behaviour of the basal end of the basilar membrane. Inversion of the spatial filter operation, although possible in theory met with difficulties in practice. The significance of slight ripples in experimental CM patterns is obscure. The direct, analytic deduction of the electrical excitation pattern from the experimental CM pattern must await the clarification of the rôle of 'ripple noise'.

The multi-electrode technique is potentially a useful tool in studies concerned with local modifications of a given electrical activity pattern. Local changes in electrical output cause a variation in the shape of the corresponding CM pattern. This was exemplified in the case of the differential growth of the activity pattern in the nonlinear range, and the cases of two-tone interaction and tonal overstimulation.

Zusammenfassung

Zur Untersuchung der Potentialverteilung entlang der Basilarmembrane wurde eine Sonde eng gesetzter Elektroden verwendet.

Die Eigenschaften der gemessenen Verteilungen bestätigen die Hypothese derzufolge die Potentialverteilung als die örtlich gefilterte Version der elektrischen Aktivität im Cortischen Organ aufgefasst werden muss. Um Aufschluss über die Reizverteilung entlang der Basilarmembran zu erhalten, wurden verschiedene hypothetische Reizverteilungen angenommen und ihre entsprechenden gefilterten Abbilder mit gemessenen Kurven verglichen. Diejenige Reizverteilung, die den Messkurven gerecht wurde, ergab zugleich eine gute Übereinstimmung mit dem in jüngster Zeit bekannt gewordenen mechanischen Verhalten der Basilarmembran am basalen Ende. — Zur direkten Ableitung der Reizverteilung von gemessenen Potentialkurven wurde die Ortsfilterfunktion invertiert. Diese Operation ist theoretisch möglich, jedoch bereitet die Inversion beträchtliche praktische Schwierigkeiten auf Grund der Unregelmässigkeiten kurzer Wellenlänge, die in den Messkurven vorliegen.

Die Elektrodensatzmethode ist besonders nützlich für Untersuchungen, die sich mit lokalen Änderungen der Reizverteilung befassen. Solche Änderungen modifizieren die Form der messbaren Potentialverteilung. Dies wurde gezeigt in den Fällen der Potentialzunahme im nichtlinearen Bereich, der Wechselwirkung zweier Töne und im Falle tonaler Überreizung.

ing in the mechanical transducer? Pumphrey & Gold (1948) (Gold & Pumphrey 1947/48) felt that they had convincing unambiguous psychoacoustic evidence for the 'resonance hypothesis. In their experiment listeners were asked to distinguish between two series of tone pulses. Each pulse consisted of n periods of a 5 kHz tone the silent interval between pulses measured m periods of the 5 kHz tone Let us call a tone pulse which begins with a positive half wave A and that with a negative half wave B Distinction had to be made between the series AAA and the series ABA. Résumé

Une technique faisant appel à une dispositif d enregistrement utilisant des electrodes multiples a été mis au point afin d étudier la répartition du potentiel microphonique dans la spire basale de la cochlée

Les caractéristiques de la répartition du potentiel microphonique provoqué par des sons sinusoïdaux sont au bon accord avec le principe de filtrage spatial. Selon ce principe on doit considérer que la répartition du potentiel microphonique représente l image de l activité électrique de l organe de Corti modifiée par un filtrage spatial Plusieurs répartitions hypothétiques ont étés proposées et confrontées avec les données experimentales concernant le potentiel microphonique. La répartition que présentait le meilleur accord avec les données récentes sur la mécanique cochléaire a été retenue L inversion du mécanisme du filtrage spatial possible en théorie, s est révelé difficilement réalisable. La signification de petites ondulations sur les graphiques representant la répartition spatiale du potentiel microphonique est difficile à expliquer

La technique des electrodes multiples apparait comme un instrument utile dans toutes les recherches consistant a décrire la répartition spatiale d une activité électrique particulière. Des changements affectant certaines sources, assez localisées, de potentiel entraine des variations importantes du pattern global du potentiel microphonique Cet effet est clairement démontré par l observation des différences dans l augmentation d amplitude du potentiel microphonique en fonction de l intensité en certains endroits, principalement dans la zone de nonlinéarité, ainsi que dans le cas des interactions entre deux fréquences, et aussi en présence d intensités excessives.

Acknowledgments

I am most grateful to Dr I C Whitfield, Director of the Neurocommunications Research Unit University of Birmingham, for his encouragement, guidance and valuable criticism throughout the course of this study

I am deeply indebted to Mr H. F Ross, Neurocommunications Research Unit, for writing the programmes for the computer aided data collection and for many inspiring discussions concerning the mathematical part of the present work.

Acknowledgment is gratefully extended to Mr D Hodges and Mr G W Hollins for their valuable contributions to the design and the expert construction of various pieces of equipment used in the study

Special thanks are due to Mrs K M Deakin, Mr T G Williamson and Mr T L Hayward for their enthusiastic assistance in the preparation of the illustrations, and to my wife for typing the manuscript

Classification and Incidence

This is the third in a series of rare tumors of the head and neck seen at this University Hospital. Moore and Arnold (47) reported 14 cases of rare tumors of the head and neck, both benign and malignant. Day and Arnold (21) reported 15 further cases of rare benign head and neck tumors. During the academic three year period 1966–1969 15 additional cases of rare malignant tumors were observed as reviewed in this paper. All of the cases were seen and treated by the Division of Otolaryngology except two. Case 8 was seen in consultation with the General Surgery Service. Case 15 was treated jointly with the Division of Plastic Surgery. In contrast to the previous publications, the patients were compiled from the University Hospital Outpatient Department (8), the Veterans Administration Hospital (3), and the private practice of the attending staff (4). This varied source may explain certain differences of distribution (age, sex, race) as compared to series I and II. The definition of a rare tumor was the same as discussed previously (47, 21).

The statistics of clinic visits, hospital admissions, and operations are listed in Table I. As was pointed out by Day and Arnold (21) there is an unusually high frequency of rare tumors for the relatively small number of total admissions to our service.

The rare malignant tumors are presented by location and type of humor. Table II summarizes the cases, including the tissue diagnosis, location, age, gender of patient, treatment, and results.

Table III compares this series with series I and II. As would be expected with malignant tumors, most of the patients were in the fifth, sixth, and seventh decades of life. In contrast to our two previous series, there is an equal distribution between white and Negro patients, which agrees with the ratio of white to Negro patients seen in our clinic.

Cancer of the Nasal Septum

Cancer of the nasal septum is a rare disease. According to Martin (42), malignant tumors of the nasal cavity and the paranasal sinuses comprise 0.2% of all cancer and 3% of cancer of the upper respiratory and alimentary tract. Nasal septal tumors are usually of the epithelial variety (48). Tumors presenting in the nasal cavity often are secondary to neoplasms of the ethmoid and maxillary sinuses, nasopharynx, orbit and external skin. With the exception of allergic and benign polyps, more than one half of the intranasal neoplasms are malignant.

The signs and symptoms of nasal malignancies vary and are very similar to many benign processes (9). Therefore, they are often overlooked in the early stages and treated conservatively. Malignant lesions are usually friable, granular, infiltrating, and bleed easily. Besides epistaxis there may be nasal obstruc

junction. Deutsch (22) reported one case and reviewed the literature, finding 27 cases of squamous cell carcinoma of the nasal septum. Lyons (37) reported seven cases of squamous cell carcinoma of the septum. Martin and Headorffer (43) reviewed the literature on malignant mixed tumors of the nasal septum. Basal cell carcinoma arises from the vestibular skin Adenocarcinoma, fibrosarcoma, lymphoepithelioma, osteogenic sarcoma, and chondrosarcoma are also seen. Occasionally the nose is the site of metastatic carcinoma.

The success of the treatment is directly proportional to the size of the lesion and the differentiation of the malignant cells Large lesions, poorly differentiated tumors, and those with local or distant spread have a poorer prognosis. Early lymphatic metastasis is not a feature of squamous cell carcinoma of the external nose (19 20). Lymphatic spread from an internal nasal tumor tends to be earlier (14) When a lesion is confined to the septum, radical neck dissection should not be performed unless nodes are palpable because nodes may appear on the contralateral side only

Malignant melanoma (19 20, 67) usually originates in the skin of the external nose but rarely occurs in the mucous membrane of the nasal cavity Malignant melanoma of the nasal cavities and paranasal sinuses is almost invariably primary and constitutes less than 2% of all malignant melanomas (67). Malignant melanomas of the nose usually spread to regional lymph nodes. Distant metastasis occurs late, which is somewhat different from the melanomas of the skin elsewhere in the body The usual sites in the nasal cavities are the anterio-inferior portions of the septum and the inferior turbinates (26, 52).

Treatment has been most successful with surgery This may be in combination with ir radiation. Large lesions which are inoperable may be palliated with irradiation. Occasionally chemotherapy may be employed. Case 1 was first treated with irradiation of a squamous cell carcinoma which failed to control the disease and radical surgery was then done without evidence of recurrence $2^1/_2$ years later Case 2 was treated only with surgery and is free of disease after 1 $/_2$ years.

Reconstruction of defects resulting from excision of carcinomas may be either immediate or delayed. Septal reconstruction often taxes the ingenuity of the surgeon. Saddling and falling of the tip is avoided by the use of a columella strut, or bone from the posterior septum. External defects may be

Fig 1 Waters view shows thickened mucosa of the maxillary sinuses. The bulbous deformity of the nose can be seen (Case 1).

closed with local flaps composite grafts fore head flaps, or tubed pedicle flaps A prosthesis can be used during the early post operative period and in certain other cases permanently

Case 1 A white man age 63 years, was referred to the ENT clinic after a biopsy from a mass in the left nasal vestibule by his local physician indicated squamous cell carcinoma. There had been a three month history of crusting ulceration and bleeding from the left nasal cavity A progressive enlargement of the tip of the nose had been noticed for about one year The patient also had paresis of his legs due to poisoning from excessive rum intake

ENT examination showed a marked enlargement and bluish discoloration of the external nose. A friable mass was present in the left nasal vestibule which arose from the nasal septum and bled freely when palpated. A hard, non tender node (1 × 1 cm) was present in the left submaxillary triangle X ray films showed the nasal mass and bilateral maxillary sinusitis (Fig 1)

The primary lesion was treated with cobalt (5 000 R) and a left radical neck dissection Three months after the cobalt treatment was completed the nasal tip became necrotic and sloughed Biopsy at the base of the nose proved recurrent squamous cell carcinoma Following radical excision of the remaining nose the patient preferred a prosthesis to plastic reconstruction of the nose He is now 2 1/2 years following resection of his nose and there is no local or distant evidence of tumor Fig 2 is a photomicrograph of the tumor

Case 2 A white woman age 60 years, con-

Fig 2 Squamous cell carcinoma of the nasal septum H and E, 100

plained of nasal obstruction Eighteen years prior to this admission she had a nasal septum tumor removed which was diagnosed as misplaced salivary gland tissue She remained asymptomatic for seven years at which time second intranasal procedure was performed Following this operation she remained free of symptoms until six months prior to admission when nasal obstruction recurred

Examination demonstrated a large midline tumor with septal deviation to the left. Paranasal sinus X-ray films showed a soft tissue fullness and distortion slightly to the right of the midline of the nasal septum A biopsy was diagnosed as malignant mixed tumor of the septum The tumor was removed through lateral rhinotomy and removal of the entire septum was necessary The patient is free of recurrence three years post op.

The tumor was composed of embryonal epithelial cells with areas of myxoid chondroid, and adenoid differentiation. The tumor cells invaded the capsule. Because of the aggressive nature and pleomorphism, the tumor was considered to be malignant. Surgical and pathologic details were reported by Martin and Hesdorffer (43).

Case 3 A white man, age 54 years, had noticed a growth on the right nasal septum for about five weeks with slight bleeding but no pain. Prior to referral, a biopsy of the lesion demonstrated malignant melanoma.

Examination showed a lesion 1 cm in dia-

plained of nasal obstruction. Eighteen years prior to this admission she had a nasal septum tumor removed which was diagnosed as misplaced salivary gland tissue. She remained asymptomatic for seven years at which time a second intranasal procedure was performed. Following this operation she remained free of symptoms until six months prior to admission when nasal obstruction recurred.

Examination demonstrated a large midline tumor with septal deviation to the left. Paranasal sinus X-ray films showed a soft tissue fullness and distortion slightly to the right of the midline of the nasal septum. A biopsy was diagnosed as malignant mixed tumor of the septum. The tumor was removed through lateral rhinotomy and removal of the entire septum was necessary. The patient is free of recurrence three years post op.

The tumor was composed of embryonal epithelial cells with areas of myxoid chondroid, and adenoid differentiation. The tumor cells invaded the capsule. Because of the aggressive nature and pleomorphism, the tumor was considered to be malignant. Surgical and pathologic details were reported by Martin and Hesdorffer (43).

Case 3 A white man, age 54 years, had noticed a growth on the right nasal septum for about five weeks with slight bleeding but no pain. Prior to referral, a biopsy of the lesion demonstrated malignant melanoma.

Examination showed a lesion 1 cm in dia-

meter on the right septum just behind the mucocutaneous junction. It was raised, irregular, hard, and had a black center. There was no bleeding and no cervical lymphadenopathy. The lesion was removed by resecting the nasal septum, columella and the skin and mucosa from the floor of the nose. Six months later he was free of local recurrence and metastasis.

Angiosarcoma

Angiosarcoma is a rare tumor in the head and neck (38). Bardwil et al. (5) at M. D. Anderson Hospital reported seven cases. A total of 155 cases have been studied in the Laboratory of Surgical Pathology of Columbia University (65). McCarthy and Pack (45) reported 20 cases, while MacComb and Martin (40) saw three cases of the nasal cavity. Most of these reports included the angiosarcoma arising anywhere in the body (24), mainly in various viscera and bones, as well as at any site in the respiratory tract (1, 40). Angiosarcoma afflicts chiefly adults without sex preponderance. The symptomatology depends on the location of the tumor. Bleeding is sometimes severe and may require ligation of major blood vessels.

Fig. 3. Proptosis and right deviation of the right eye caused by an angiosarcoma of the right paranasal sinuses (Case 4).

Angiosarcoma is also called hemangiosarcoma, malignant hemangioendothelioma, angiofibrosarcoma, hemangioblastoma, hemangioendothelioblastoma, and hemangioendothelioma (65). Its histogenesis is obscure, as suggested by the number of its various names. The concept of the so-called benign metastasizing hemangioma is now generally discredited. Since one can distinguish small blood vessels from lymph vessels only by their contents, the presence of blood in some vessels and protein in others suggests that the tumor may be produced from both blood and lymph vessels (5, 62, 65).

Microscopically, conglomerates of atypical capillaries with a marked tendency to frequent anastomosis predominate. These capillaries are lined with swollen, anaplastic endothelioblasts, which are either rounded or elongated and sometimes accumulated in clumps, partly filling the lumen. A reticulum stain will demonstrate the vascular pattern showing the tumor cells inside the delicate reticulum sheath that encloses each vessel.

The clinical course of these tumors varies. There is a strong tendency to recur locally as well as to metastasize. Metastasis usually takes the hematogenous route, but may be lymphatically spread as well. When feasible,

the treatment of choice is complete excision of the tumor Radical neck dissection is done in cases of controlled primary lesion with cervical metastasis. Irradiation occasionally produces a favorable response (27 45 51). Its prognosis again varies, but the largest series of 155 cases (65) reflected mortality of 56% among adults.

Case 4 A Negro woman, age 47 years (Fig. 3) had a two month history of right proptosis, tearing, sinus trouble" bloody nasal discharge on the right, and a lump in the right neck. Weight loss or impairment of vision were denied. The patient had conservative treatment by a local physician for a short period without response before seeking help at the Medical Center

Examination showed right proptosis, bilateral submaxillary lymphadenopathy (more on the right side) but no lesions could be seen intranasally The sinus x ray films demonstrated clouding of the ethmoids and maxillary sinus, and erosion of the inferiomedial wall of the right orbit, all on the right A biopsy from the right maxillary sinus and ethmoid cells was diagnosed as a poorly differentiated carcinoma. Following reticulum stain of the specimen it was diagnosed as an angiosarcoma.

The patient received 5 000 R cobalt radiation to the right orbital and maxillary region during 13 treatments. The proptosis regressed greatly and the cervical lymphadenopathy disappeared. Right radical maxillectomy was well tolerated with uneventful recovery However three months post op. the patient began to lose weight and pulmonary and cervical metastases appeared. Chemotherapy brought no improvement and the patient died a few weeks later Fig. 4 is a photomicrograph of the tumor

Fig 4 The vascular spaces of the angiosarcoma lined with endothelial cells. H and E, 475

Rhabdomyosarcoma

The first series of our rare tumors (47) contained two cases of rhabdomyosarcoma, one in the middle ear of a 2 year old Negro boy and the other in the nasopharynx of a 16 year old Negro girl. Two varieties of rhabdomyosarcoma are recognized. the form found almost exclusively in children, and the adult type almost exclusively in adults. The 474 cases described by Stout (63 65) had this distribution. 236 in the age group below 15 years, and 238 above. Horn and Enterline (33) observed 39 cases with 18 below age 16 and 21 above.

Rhabdomyosarcoma is the most common

meter on the right septum just behind the mucocutaneous junction. It was raised, irregular hard and had a black center There was no bleeding and no cervical lymphadenopathy The lesion was removed by resecting the nasal septum, columella and the skin and mucosa from the floor of the nose. the treatment of choice is complete excision of the tumor Radical neck dissection is done in cases of controlled primary lesion with cervical metastasis. Irradiation occasionally produces a favorable response (27 45 51) Its prognosis again varies, but the largest series of 155 cases (65) reflected mortality of 56% among adults.

Case 4 A Negro woman, age 47 years (Fig. 3), had a two month history of right proptosis, tearing, "sinus trouble bloody nasal discharge on the right, and a lump in the right neck. Weight loss or impairment of vision were denied. The patient had conservative treatment by a local physician for a short period without response before seeking help at the Medical Center

Examination showed right proptosis, bilateral submaxillary lymphadenopathy (more on the right side) but no lesions could be seen intranasally The sinus x ray films demonstrated clouding of the ethmoids and maxillary sinus, and erosion of the inferiomedial wall of the right orbit, all on the right. A biopsy from the right maxillary sinus and ethmoid cells was diagnosed as a poorly differentiated carcinoma. Following reticulum stain of the specimen it was diagnosed as an angiosarcoma.

The patient received 5 000 R cobalt radiation to the right orbital and maxillary region during 13 treatments. The proptosis regressed greatly and the cervical lymphadenopathy disappeared. Right radical maxillectomy was well tolerated with uneventful recovery However three months post op. the patient began to lose weight and pulmonary and cervical metastases appeared. Chemotherapy brought no improvement and the patient died a few weeks later Fig 4 is a photomicrograph of the tumor

Fig 4 The vascular spaces of the angiosarcoma lined with endothelial cells. H and E, 475

Rhabdomyosarcoma

The first series of our rare tumors (47) contained two cases of rhabdomyosarcoma, one in the middle ear of a 2 year old Negro boy and the other in the nasopharynx of a 16 year old Negro girl. Two varieties of rhabdomyosarcoma are recognized. the form found almost exclusively in children, and the adult type almost exclusively in adults. The 474 cases described by Stout (63 65) had this distribution. 236 in the age group below 15 years, and 238 above. Horn and Enterline (33) observed 39 cases with 18 below age 16 and 21 above.

Rhabdomyosarcoma is the most common

meter on the right septum just behind the mucocutaneous junction. It was raised, irregular hard, and had a black center. There was no bleeding and no cervical lymphadenopathy. The lesion was removed by resecting the nasal septum, columella, and the skin and mucosa from the floor of the nose. Six months later he was free of local recurrence and metastasis.

Angiosarcoma

Angiosarcoma is a rare tumor in the head and neck (38). Bardwil et al. (5) at M. D. Anderson Hospital reported seven cases. A total of 155 cases have been studied in the Laboratory of Surgical Pathology of Columbia University (65). McCarthy and Pack (45) reported 20 cases, while MacComb and Martin (40) saw three cases of the nasal cavity. Most of these reports included the angiosarcoma arising anywhere in the body (24) mainly in various viscera and bones, as well as at any site in the respiratory tract (1, 40). Angiosarcoma afflicts chiefly adults without sex preponderance. The symptomatology depends on the location of the tumor. Bleeding is sometimes severe and may require ligation of major blood vessels.

Fig. 3. Proptosis and right deviation of the right eye caused by an angiosarcoma of the right paranasal sinuses (Case 4).

Angiosarcoma is also called hemangiosarcoma, malignant hemangioendothelioma, angiofibrosarcoma, hemangioblastoma, hemangioendothelioblastoma, and hemangioendothelioma (65). Its histogenesis is obscure as suggested by the number of its various names. The concept of the so-called benign metastasizing hemangioma is now generally discredited. Since one can distinguish small blood vessels from lymph vessels only by their contents, the presence of blood in some vessels and protein in others suggests that the tumor may be produced from both blood and lymph vessels (5, 62, 65).

Microscopically conglomerates of atypical capillaries with a marked tendency to frequent anastomosis predominate. These capillaries are lined with swollen anaplastic endothelioblasts, which are either rounded or elongated and sometimes accumulated in clumps, partly filling the lumen. A reticulum stain will demonstrate the vascular pattern showing the tumor cells inside the delicate reticulum sheath that encloses each vessel.

The clinical course of these tumors varies. There is a strong tendency to recur locally as well as to metastasize. Metastasis usually takes the hematogenous route but may be lymphatically spread as well. When feasible

Malignant Tumors of the Major Salivary Glands

No tumors of the major salivary gland occurred in either of the two previous reports of rare tumors of the head and neck (21 47). It was observed at the M. D. Anderson Hospital (56) (1944 to 1962), that 4.5% of the total number of patients with malignant tumors of the head and neck had malignant tumors of the salivary glands. Less than 1% of all cancer cases are located in the salivary glands (41). Frazell (29) found 36% of 1751 major salivary gland tumors to be malignant. Among all these tumors, 88% were located in the parotid, and about one third of these were malignant. The submaxillary gland tumors represented only 11.8% of the total, but 53% of these were malignant. Tumors of the sublingual gland numbered only four (0.2%) and all were malignant.

We had four patients with malignant salivary gland tumors: an adenocarcinoma of the parotid gland, a mucoepidermoid carcinoma of the parotid gland, a malignant mixed tumor of the submaxillary gland and a mucoepidermoid carcinoma of both submaxillary glands. There are numerous reports of the first three types of tumors. However we could not find a case report of a mucoepidermoid carcinoma of both submaxillary glands occurring simultaneously. Bilateral occurrence of papillary cystadenoma lymphomatosum (Warthin's tumor) has been reported (70, 15). Frazell (29) had 1 patients with multiple salivary gland tumors in his series of 1751. Of these 16 had bilateral Warthin's tumors in the parotid, and two bilateral mixed tumors in the parotid. Another patient had a benign mixed tumor in one parotid and one submaxillary gland. One patient had bilateral lymphoepithelial lesions of the parotids. The last patient had an acinic carcinoma of the parotid and benign mixed tumor of the submaxillary glands.

In the past there was disagreement concerning the histogenesis and the criteria for histologic classifications. Some of the parotid tumors are still difficult to place in any classification. Work and Gates (69) have outlined a clinically useful classification, dividing the tumors into four groups. (1) epithelial cell origin, (2) supporting tissue origin, (3) local manifestation of constitutional disease, and (4) metastatic disease. The AFIP fascicle by Foote and Frazell (28) is one of the best guides for histologic classification.

The treatment of malignant salivary gland tumors is well described (3 4 8, 19 25 30, 56, 69). It is primarily surgical. Radiotherapy has been employed for palliation of non-resectable tumors, for recurrences, and for post operative cases when the margins contained tumor

The reports of results vary greatly Malignant tumors arising in the submaxillary and

Fig. 6. Case 6, showing right parotid mass which was an adenocystic carcinoma of the parotid.

Fig 5 19 month old girl with lateral displacement of the left eye (Case 5).

malignant head and neck tumor except in the brain (63) Its two types differ also in location In the older age group the primary lesions predominate in the torso and extremities. The primary areas afflicted by the juvenile type involve the head and neck or urogenital tract (61) Both types have a poor prognosis. In the infantile variety the orbit is a typical site where this relatively rare tumor occurs. Porterfield and Zimmerman (55) reported 55 such cases. Local spread proceeds through direct infiltration. Distant metastasis follows the hematogenous and less commonly the lymphatic route Metastases are found in the lungs, lymph nodes, skin subcutaneous tissues, pleura, bones, liver kidney adrenals mediastinum, pericardium pancreas, ovary and brain in that order

The microscopic appearance varies greatly The tumor has been given different names —botryoid embryonal alveolar and pleomorphic—expressing certain gross and microscopic features that characterize these varieties (23 33) The greatest overlap of features concerns the first three varieties and characteristics of each may occur in the same tumor For this reason the term juvenile rhabdomyosarcoma has been proposed (65). The term "pleomorphic is often applied only to the adult type (63)

Treatment of these tumors has not been very successful (64 66) Radiotherapy can be administered preoperatively postoperatively as the sole treatment, or for palliation. When advocated surgery attempts wide resection. However one should be reasonably certain of a cure before performing extensive and mutilating surgery especially in children. Chemotherapy has temporarily produced remissions of local recurrences and metastatic lesions. It may be given to augment the beneficial effects of irradiation Actinomycin D vincristine, and cyclophosphamide (Cytoxan) are the drugs usually administered for this tumor

Case 5 A white girl, age 19 months, was noted to have left orbital swelling and mild, bilateral bloody nasal discharge for one month There was no weight loss, pain or evidence of infection We saw this patient in consultation with ophthalmology and noted lateral displacement of the eye by an orbital mass on the left side (Fig. 5).

Vision and ocular motility were good. Orbital biopsy disclosed the alveolar embryonal type of rhabdomyosarcoma.

The patient received 1800 R cobalt to the left orbital area preoperatively followed by left orbital exenteration left ethmoidectomy and partial maxillectomy The specimen showed post irradiation changes, but some tumor fragments were found. Three days post op a program of chemotherapy was begun with vincristine, actinomycin D and Cytoxan* which had been continued on an outpatient basis. No recurrence nor metastasis was noted eight months later

perineural invasion. The diagnosis was low ...de adenocarcinoma of the parotid gland.

Case 7 A Negro girl, age 18 years, was ...erred to the ENT clinic for evaluation of ...rvical lymphadenopathy Five months pre...ously she had received x-ray treatment by ...r local physician after a tissue diagnosis of ...rcinoma of the skin behind the right ear ...d been made. An enlarging mass behind ...e right ear of five years duration, a three ...ear history of right facial nerve paralysis, ...nd bilateral temporal headaches with occa...ional tinnitus in the right ear had prompted ...er original visit.

Examination showed multiple nodularity in ...he right posterior triangle, mild tenderness ...ver the tail of the parotid gland, and right peripheral facial nerve paralysis. An audiogram and sinus x-ray films were normal.

Total excision of the right parotid gland and right neck dissection were performed. Wide skin excision over the mastoid area, including part of the auricle, was necessary and a split thickness skin graft was applied. Following removal of the specimen, it was noted that the tumor had invaded the jugular foramen. Eight of the 15 lymph nodes contained tumor The tissue diagnosis was mucoepidermoid carcinoma of the parotid gland. The patient received cobalt therapy postoperatively because tumor had remained in the jugular foramen. Twenty-one months postoperatively a recurrence under the right ear was treated with 5-fluorouracil. The chemotherapy was not completed and the patient could not be traced.

Case 8. A Negro woman, age 21 years, had a two year history of a right submandibular mass (Fig. 9) with a period of rapid growth eight months before being seen. She was pregnant during that time and delivered a normal infant two months before being seen. The remainder of the past history and systems review was normal. We saw the patient in consultation with the General Surgery Service for laryngoscopy and nasopharyngoscopy

Examination showed a large, firm, non-

Fig. 9 Malignant mixed tumor of the right submaxillary gland (Case 8).

tender fixed mass in the right submandibular area which displaced the tongue, bulged into the hypopharynx on the right side, and invaded the floor of the mouth on the right. It extended across the midline submentally but there were no palpable nodes in the neck. The tentative diagnosis considered a salivary gland tumor and the history of recent rapid growth suggested a malignant lesion.

At surgery the huge lesion was found to involve the anatomical areas mentioned above. Frozen section of the lesion was reported as malignant tumor involving the submandibular gland. The tumor was incompletely excised at the base of the tongue. The diagnosis from the permanent slides was malignant mixed tumor of the salivary gland. The patient was then treated with cobalt (3000 R) and radical resection of the lesion was completed. She died on the second postoperation day from uncontrollable hemorrhage that could not be anticipated.

Fig Low grade adenocarcinoma of the parotid gland shows invasion of the capsule H and E, 50

sublingual glands are not only more frequent *but also* more aggressive than similar tumors of the parotid gland. The five year survival for the lower grade parotid tumors is about 80% to 85% but drops sharply in the more malignant group. Local recurrence and regional spread to lymph nodes is not uncommon. Some of the tumors, like adenocarcinomas, produce bloodborne metastasis.

Case 6 A Negro man age 44 years, was referred to the ENT clinic because of a mass under the right ear (Fig 6) This mass had been present for about one year and had been completely asymptomatic. The past history was not remarkable.

Examination showed a firm slightly moveable non-tender mass inferior and slightly anterior to the right auricle Saliva from the right parotid duct was clear There was no facial nerve impairment. A tentative diagnosis of a malignant parotid tumor was made because of the rapid growth. A sialogram demonstrated the mass to be fairly discrete and located in the deep portion of the parotid gland.

A total parotidectomy was done with preservation of the facial nerve. The tumor was indeed located in the deep portion of the parotid gland and was very well circumscribed. Some transient paresis of the frontal and zygomatic branches of the facial nerve was noted post-operatively

Figs. 7 and 8 show *the microscopic appearance of the malignant portion of the tumor The tumor had a variable pattern. The* nuclei exhibited variation in size, with some pleomorphism and hyperchromatism. Occasional mitoses were present. The tumor invaded the capsule but the resection margins were free of tumor There was no vascular

Fig 8 Adenocarcinoma of the right parotid gland shows pleomorphism and hyperchromatism. Rare mitosis and cystic structure can be seen. H and E, 475

mors in the buccal area represented mucoepidermoid carcinoma. In the lip two thirds of all tumors were benign, malignant mixed tumor and adenocarcinoma represented the majority of the remaining third of labial malignant tumors.

The symptomatology and signs in these patients depend on the location of the tumor. The lesions of the oral cavity appear as a painless mass. Patients with intranasal and nasopharyngeal tumors have epistaxis, nasal obstruction, pain, and nasal discharge. Hypopharyngeal and laryngeal tumors manifest themselves through symptoms of dysphagia, "sore throat," and hoarseness. Occasionally the malignant tumors become manifest as metastasis in a cervical node or less commonly at distant sites.

The types of minor salivary gland tumors are classified as adenoid cystic carcinoma, benign mixed tumor, malignant mixed tumor, mucoepidermoid carcinoma, and adenocarcinoma (1, 6, 58). The prognosis of the malignant tumors of the minor salivary glands is poorer than with the malignant tumors of the major salivary glands. Surgical resection is the treatment of choice for the untreated malignant tumors and for resectable local recurrences. Radiotherapy has been used preoperatively for local recurrences not amenable to excision, and for palliation. It has also been used postoperatively after incomplete removal of the tumor.

Case 10. A Negro man, age 52 years, was seen in the ENT clinic complaining of right nasal obstruction which had been present for about three months. The onset was insidious and non-relenting. There was a small amount of blood-tinged mucus, but no pain, hearing loss, nor history of trauma. The past history was unremarkable.

Examination showed a lobulated, red mass (1 2 cm) in the right choana which originated from the floor of the nose and extended onto the right inferior turbinate. Serous otitis was not present. A transnasal biopsy demonstrated adenocystic carcinoma. Sinus x ray films and contrast studies of the sinuses excluded their involvement. The tumor mass was removed from the nose through right lateral rhinotomy. It was found to be attached to the floor of the nose and the posterior border of the inferior and middle turbinates. The patient is free of recurrence three years post op.

The tumor was described as being a moderately cellular glandular tumor presenting a distinct cribriform pattern. There were cords and nests of small cells with hyperchromatic nuclei. Mitotic activity was not seen.

Case 11. A white man, age 64 years, complained of a "scratchy feeling" in the left side of his throat for some six months. Initial examination showed a small, whitish, round (2 × 3 mm) growth on the ventricular fold anterior to the left arytenoid cartilage. The cartilage moved well, the vocal cord was normal, and the voice clear. The patient had had a spontaneous pneumothorax some five years earlier supposedly from emphysema. He had smoked excessively for many years.

A biopsy of the lesion was reported as a mixed tumor of a minor salivary gland, but it was not certain whether it was benign or malignant. Under general anesthesia, the larynx was opened through laryngofissure, the entire left ventricular fold and the suprastructure of the left arytenoid cartilage were removed while preserving the vocal process and cord.

Although the tumor was adequately excised, considerable discussion regarding the pathological diagnosis ensued. The slides were sent to AFIP and the final consensus of opinion established a malignant mixed tumor of a minor salivary gland. The patient has been free of disease for four years.

Case 9 A white man age 63 years, was admitted to the ENT service with a 2 1/2 year history of bilateral submandibular swelling. These masses began as small nodules and gradually increased in size There was no history of pain, bleeding, or abnormal saliva tion. Weight loss of 18 pounds occurred over the past two years. The remainder of the past history was unremarkable.

Examination showed bilateral submandibular masses. Each was about 4 × 5 cm in size and was slightly lobulated with cystic areas. There was no cervical lymphadenopathy Chest x ray films demonstrated a moderate amount of pulmonary fibrosis without evidence of metastatic disease Sinus x ray films were normal. No primary lesion could be detected, nor was there evidence of metastatic disease. After a biopsy had indicated mucoepidermoid carcinoma, both submandibular masses were widely excised.

Several months later the patient developed posterior and anterior cervical adenopathy Lymph node biopsy was reported as carcinoma. The results of further examinations of nasopharynx, oropharynx and sinuses were normal. The patient then received 5000 R cobalt with good initial response. However two months later local recurrence occurred at the angle of the left mandible and multiple metastatic nodules were scattered throughout both lung fields. The patient died from his disease 15 months after excision of the tumors.

Malignant Tumors of the Minor Salivary Glands

Our first series of rare tumors (47) reported three tumors of the minor salivary glands, two benign mixed tumors of the soft palate, and one adenocarcinoma of the hard palate. This present series includes three patients one with adenoid cystic carcinoma of the nasopharynx, another with a malignant mixed tumor of the ventricular fold and a mixed tumor of the nasal septum. The latter tumor was discussed above in the section of Tumors of the Nasal Septum

Tumors of the minor salivary glands occur with significant frequency in the upper respiratory tract. They are morphologically similar to those that arise in the major salivary glands (28) The tumor usually arises from accessory salivary glands or from mucous glands (1) These tumors, both benign and malignant occur predominantly in males, mostly in patients 40 to 60 years of age The most common tumor type and the most frequent location vary among reports. Common sites are the palate nasopharynx, alveolus, tongue sinuses, nasal septum oral mucosa tonsil, pharynx (oro- and hypo-) and the larynx. The larynx is an uncommon location for this rare tumor Sabri and Hajjar (57) reported a case of malignant mixed tumor of the vocal cord and found 37 cases reported in the world literature.

Conley (17) found that tumors of the minor salivary glands were about five times less common than parotid tumors which constitute approximately 88% of all major salivary gland tumors. He stated that 56% of the minor salivary gland tumors were malignant. Moreover 55% of all minor salivary gland tumors were found in females and they were most common in the fifth decade of life. More than half of the tumors occurred in the palate and 58% of these were malignant In the group of tumors of the tongue floor of the mouth and alveolus, 95% were malignant The percentage of malignancy for the buccal area, lip, and nasal cavity was 65% 35% and 50% respectively The predominant carcinoma in the palate and the nasal cavity was adenoid cystic carcinoma while the majority of tu-

mors in the buccal area represented mucoepidermoid carcinoma. In the lip two thirds of all tumors were benign, malignant mixed tumor and adenocarcinoma represented the majority of the remaining third of labial malignant tumors.

The symptomatology and signs in these patients depend on the location of the tumor. The lesions of the oral cavity appear as a painless mass. Patients with intranasal and nasopharyngeal tumors have epistaxis, nasal obstruction, pain, and nasal discharge. Hypopharyngeal and laryngeal tumors manifest themselves through symptoms of dysphagia, "sore throat," and hoarseness. Occasionally the malignant tumors become manifest as metastasis in a cervical node or less commonly at distant sites.

The types of minor salivary gland tumors are classified as adenoid cystic carcinoma, benign mixed tumor, malignant mixed tumor, mucoepidermoid carcinoma, and adenocarcinoma (1, 6, 58). The prognosis of the malignant tumors of the minor salivary glands is poorer than with the malignant tumors of the major salivary glands. Surgical resection is the treatment of choice for the untreated malignant tumors and for resectable local recurrences. Radiotherapy has been used preoperatively for local recurrences not amenable to excision, and for palliation. It has also been used postoperatively after incomplete removal of the tumor.

Case 10 A Negro man, age 52 years, was seen in the ENT clinic complaining of right nasal obstruction which had been present for about three months. The onset was insidious and non-relenting. There was a small amount of blood-tinged mucus, but no pain, hearing loss, nor history of trauma. The past history was unremarkable.

Examination showed a lobulated, red mass (2 × 2 cm) in the right choana which originated from the floor of the nose and extended onto the right inferior turbinate. Serous otitis was not present. A transnasal biopsy demonstrated adenocystic carcinoma. Sinus x-ray films and contrast studies of the sinuses excluded their involvement. The tumor mass was removed from the nose through right lateral rhinotomy. It was found to be attached to the floor of the nose and the posterior border of the inferior and middle turbinates. The patient is free of recurrence three years post op.

The tumor was described as being a moderately cellular glandular tumor presenting a distinct cribriform pattern. There were cords and nests of small cells with hyperchromatic nuclei. Mitotic activity was not seen.

Case 11 A white man, age 64 years, complained of a "scratchy feeling" in the left side of his throat for some six months. Initial examination showed a small, whitish, round (2 × 3 mm) growth on the ventricular fold anterior to the left arytenoid cartilage. The cartilage moved well, the vocal cord was normal, and the voice clear. The patient had had a spontaneous pneumothorax some five years earlier supposedly from emphysema. He had smoked excessively for many years.

A biopsy of the lesion was reported as a mixed tumor of a minor salivary gland, but it was not certain whether it was benign or malignant. Under general anesthesia, the larynx was opened through laryngofissure, the entire left ventricular fold and the suprastructure of the left arytenoid cartilage were removed while preserving the vocal process and cord.

Although the tumor was adequately excised, considerable discussion regarding the pathological diagnosis ensued. The slides were sent to AFIP and the final consensus of opinion established a malignant mixed tumor of a minor salivary gland. The patient has been free of disease for four years.

Adenocarcinoma of the Tongue

Malignant tumors of the tongue are quite frequent. The incidence varies with geographic location from 1% of all cancer deaths in the United States to 14% as reported from India (54). About 95% of all lingual cancers are of squamous cell or epidermoid type (23, 39). The other 5% consist of rhabdomyosarcomas and tumors of minor salivary glands. When Gobbel et al. (31) reported 100 cases of tongue cancer, 109 of these were squamous cell carcinomas and only one was a rhabdomyosarcoma. Owen (50) found that the adeno-cell type constituted less than 2% of all carcinomas of the tongue. Burbank et al. (12) reported on 43 glandular tumors of the tongue observed among more than 3 800 cases of benign and malignant lesions of the tongue. Twenty two (51%) of these 43 tumors were cylindromas which are the most common glandular tumors, eleven (26%) were of mucoepidermoid type, nine (21%) were adenocarcinomas, the remaining glandular lesion was a mixed tumor. Harrold (32) reported 281 patients with cancer of the base of the tongue and 7% of these showed adenocarcinoma.

Watson (68), in his series of 41 intra-oral adenocarcinomas, found that 17% of the tumors involved the base of the tongue. Burbank et al. (12) noted that some of these adenocarcinomas strongly resembled thyroid adenocarcinoma. An origin from lingual thyroid tissue suggests an attractive but unproven hypothesis, especially of those tumors at the base of the tongue.

Good results can be obtained with radical surgery of the glandular tumors. The results depend on the anaplasticity of the tumors, their size and the spread. Five of the nine patients with adenocarcinoma reported by Burbank et al. (12) died of their disease seven months to seven years after treatment. The four who lived were seen 3 to 16 years after treatment.

Case 12. A white man, age 83 years, noticed a small raised lesion on the right side of his tongue 1 $^1/_2$ to 2 years before seeking medical advice. During the recent weeks prior to treatment, this lesion became ulcerated and was mildly uncomfortable. The patient had been a pipe smoker for many years, his daughter had died of tongue cancer and he had a weight loss of 17 pounds in two months.

Examination showed a large, ulcerated, indurated lesion on the right margin of the tongue, extending to the border of its anterior one third and posteriorly to the circumvallate line. It extended downward to the floor of the mouth but not to the mandible and deep inside the tongue. There was a large fixed node in the right submandibular area. The man also had a small hemangioma on the right lower lip, another on the left upper lip, and still a third on the right base of the tongue. A biopsy of the mass showed adenocarcinoma. It was classified as $T_3N_1M_0$, Stage III.

The patient was advised to have preoperative radiotherapy followed by a hemiglossectomy, right partial mandibulectomy and right radical neck dissection. He refused this plan and was treated with external radiotherapy resulting in an excellent regression of the primary lesion. However, cervical nodes did reappear, a radical neck dissection was performed, and radium needles were placed into the tongue. Fifteen of the 44 cervical lymph nodes contained metastatic tumor. The patient was free of tumor for two years, but later he could no longer be traced by mail.

Adenoid Cystic Carcinoma of the External Auditory Canal

The external auditory canal is lined with skin that is continuous with the skin of the auricle. The skin covering the cartilaginous portion of the meatus contains hair follicles, sebaceous glands, and modified sweat glands or ceruminal glands. It is from these structures that glandular tumors of the external auditory canal originate.

The exact incidence of cancer of the external auditory canal is uncertain for several reasons. Case reports are isolated and not always well documented. Some larger series fail to separate external auditory canal lesions from middle ear and mastoid lesions. Broders (11) estimated that 84% of aural cancer involved the auricle, slightly more than 14% the auditory canal, and less than 2% the middle ear and mastoid. There is no sex predominance in carcinoma of the external auditory canal (35). Most of the tumors occur between the ages of 45 and 65.

The malignant tumors of external auditory canal can be divided into epithelial tumors and mesenchymal tumors (35). The epithelial tumors include squamous cell carcinoma, basal cell carcinoma, and malignant melanoma. The glandular tumors arise from the glands mentioned above and are classified as adenocarcinoma, also called adenoid cystic carcinoma, cylindroma, adenomyoepithelioma, and basiloma (60). Ash et al. (1) consider the ceruminoma to be a benign tumor stating that they had no record of an authentic ceruminal gland tumor that had metastasized. Batsakis et al. (7) considered one of their two reported cases of "ceruminomas" to be malignant on the basis of local aggressiveness and infiltration. O'Neal and Parker (49) found ceruminous gland tumors to carry a poor prognosis.

The treatment of malignant tumors of the external auditory canal is excision with adequate margins of those tumors that are limited to the external canal and do not invade the cartilaginous or bony capsule. Unfortunately many cases represent advanced tumors with extension into the middle ear and temporal bone. A mastoidectomy in combination with removal of the external auditory canal sometimes adequately removes the tumor. Parsons and Lewis (53) advocated a subtotal resection of the temporal bone after Campbell et al. (13) had originally described a total resection for more extensive neoplasms. Radiation has been used preoperatively, postoperatively, as the sole means of treatment, and for palliation.

We had two patients with a malignancy of the external canal, one with an adenocystic carcinoma and the other with a ceruminoma. The ceruminoma is exceedingly rare and will be published in detail by Louis and Smith (36).

Case 13. A Negro man, age 48 years, complained of intermittent throbbing pain in the left ear of one year's duration. There had been a rapid deterioration of hearing in that ear during the preceding three months as well as an intermittent bloody discharge. His local physician biopsied a lesion in the external auditory canal which was diagnosed as adenocystic carcinoma. He was referred to the ENT service for further management. The remaining past history was unremarkable.

Examination was normal except for the findings in the left ear. There was frequent bleeding within the ear canal. The left tympanic membrane was eroded by a grayish papillary growth extruding from the middle ear. There was no evidence of purulence or adenopathy. Mastoid x-ray films demonstrated clouding on the left with loss of the cellular structure (Figs. 10–11). The skull x-ray films were normal.

The patient underwent a left radical mas-

Adenocarcinoma of the Tongue

Malignant tumors of the tongue are quite frequent. The incidence varies with geographic location from 1% of all cancer deaths in the United States to 14% as reported from India (54). About 95% of all lingual cancers are of squamous cell or epidermoid type (23, 39). The other 5% consist of rhabdomyosarcomas and tumors of minor salivary glands. When Gobbel et al. (31) reported 100 cases of tongue cancer, 109 of these were squamous cell carcinomas and only one was a rhabdomyosarcoma. Owen (50) found that the adeno-cell type constituted less than 2% of all carcinomas of the tongue. Burbank et al. (12) reported on 43 glandular tumors of the tongue observed among more than 3 800 cases of benign and malignant lesions of the tongue. Twenty-two (51%) of these 43 tumors were cylindromas which are the most common glandular tumors, eleven (26%) were of mucoepidermoid type, nine (21%) were adenocarcinomas, the remaining glandular lesion was a mixed tumor. Harrold (32) reported 281 patients with cancer of the base of the tongue and 7% of these showed adenocarcinoma.

Watson (68), in his series of 41 intra-oral adenocarcinomas, found that 17% of the tumors involved the base of the tongue. Burbank et al. (12) noted that some of these adenocarcinomas strongly resembled thyroid adenocarcinoma. An origin from lingual thyroid tissue suggests an attractive but unproven hypothesis, especially of those tumors at the base of the tongue.

Good results can be obtained with radical surgery of the glandular tumors. The results depend on the anaplasticity of the tumors, their size, and the spread. Five of the nine patients with aden carcinoma reported by Burbank et al. (12) died of their disease seven months to seven years after treatment. The four who lived were seen 3 to 16 years after treatment.

Case 12. A white man, age 83 years, noticed a small raised lesion on the right side of his tongue $1\,^1/_2$ to 2 years before seeking medical advice. During the recent weeks prior to treatment, this lesion became ulcerated and was mildly uncomfortable. The patient had been a pipe smoker for many years, his daughter had died of tongue cancer, and he had a weight loss of 17 pounds in two months.

Examination showed a large, ulcerated, indurated lesion on the right margin of the tongue extending to the border of its anterior one third and posteriorly to the circumvallate line. It extended downward to the floor of the mouth but not to the mandible and deep inside the tongue. There was a large fixed node in the right submandibular area. The man also had a small hemangioma on the right lower lip, another on the left upper lip and still a third on the right base of the tongue. A biopsy of the mass showed adenocarcinoma. It was classified as $T_2N_1M_0$, Stage III.

The patient was advised to have preoperative radiotherapy followed by a hemiglossectomy, right partial mandibulectomy and right radical neck dissection. He refused this plan and was treated with external radiotherapy resulting in an excellent regression of the primary lesion. However, cervical nodes did reappear, a radical neck dissection was performed, and radium needles were placed into the tongue. Fifteen of the 44 cervical lymph nodes contained metastatic tumor. The patient was free of tumor for two years, but later he could no longer be traced by mail.

tion. She did not have vertigo, ear drainage, or history of trauma to her head or ear. There was no family history of hearing loss.

Examination revealed a granulomatous tissue filling the right external ear canal. There was partial paralysis (peripheral type) of the fifth and seventh nerves and a conductive hearing loss, all on the right side. Mastoid X-ray films demonstrated clouding of the mastoid air cells with destruction of some of the bony septa. The patient was thought to have chronic otitis media with cholesteatoma.

Radical mastoidectomy was performed during which a frozen section of the tissue was reported as a neoplasm. Permanent sections of the tumor were diagnosed as ceruminoma. Tomograms of the right temporal bone showed involvement of the petrous apex. A partial abducens nerve paralysis developed on the right side two weeks after surgery and disappeared three months later believed to be due to petrositis. The patient was treated with radiotherapy postoperatively. Seven months later a recurrence of the ceruminoma appeared in the right nasopharynx and tomographic films showed advanced destruction around the apex of the temporal bone.

Malignant Melanoma of the Hard Palate

Malignant melanoma was discussed at the beginning of this paper in connection with the nasal septum. This unpredictable tumor constitutes about 1.5% of human cancers and approximately 20% of all melanomas occur in the region of the head and neck (18). Melanoma of the oral cavity is very rare. Most of the melanomas of the mucous membrane occur in the nose and sinuses. Only one melanoma of the hard palate was discovered in the M. D. Anderson Hospital series (2). Simons (59) reported 257 patients with malignant melanoma of the head and neck seen at the Mayo Clinic from 1950 through 1967. He had only two patients in whom the melanoma arose from the intraoral mucous membrane, but the exact site was not mentioned.

Chaudhry et al. (16) in a detailed review of 105 cases of malignant melanoma of the oral cavity found 38 cases involving the hard palate. They found oral cavity melanomas to occur twice as often in males. The average age was 50.5 years and a marked tendency for both regional as well as distant metastasis was noted. The prognosis for oral mucosal melanomas is much more serious than that of cutaneous melanomas.

Moore and Martin (46) reported 1 546 patients with malignant melanoma seen at the Memorial Hospital Center from 1930 through 1948. Among these, 492 (27.6%) involved the head and neck region, but only 27 (1.7%) originated in the oral and upper respiratory tract. Three of these lesions were located in the hard palate.

Case 15. A Negro man, age 62 years, was seen at the Medical Center for a neck mass which had been present for about three months. A biopsy of a pigmented, ulcerative

Fig. 12. Malignant melanoma of the hard palate, metastatic to the lymph nodes of the anterior triangle of the left neck (Case 15).

Fig. 10. Law projection of both mastoids shows a loss of the cellular structure and clouding of the left mastoid (Case 13).

toidectomy and the tumor was incompletely resected because of extension into the labyrinth and cochlea. The patient received 5000 R cobalt to the left temporal area.

The patient was readmitted one year later because of the development of hoarseness and extensive left cervical adenopathy. X-ray films showed progressive destruction in the region of the left mastoid and petrous bone. The left vocal cord was paralyzed in the paramedian position and did not move for phonation. The left neck mass proved to be metastatic adenoid cystic carcinoma. The man eventually developed massive recurrence of the tumor and died 23 months after diagnosis.

Case 14. A Negro woman, age 50 years, complained of a gradual hearing loss, tinnitus, and right sided headaches of three years dura-

Fig. 11. The right mastoid is normal (Case 13).

among the male (11 9), again the Negro (12: 8), but in the older age groups (14 6).

There have been few reports of bilateral salivary gland tumors. Bilateral papillary cystadenoma lymphomatosum (Warthin's tumor) is well known. As stated before, Frazell (29) saw 21 patients with multiple salivary gland tumors. Sixteen of these had bilateral Warthin's tumors in the parotid gland. One patient had an acinic carcinoma of the parotid and benign mixed tumor of the submaxillary glands. The simultaneous, bilateral occurrence of a mucoepidermoid carcinoma of both submaxillary glands in our case 9 is certainly rare as far as we could ascertain this is the first report of such a case.

Summary

This is the third of a series of rare tumors of the head and neck. The first series contained nine benign and five malignant tumors of rare type. The second series presented 15 benign tumors. The 15 cases reported in this paper are all rare malignant tumors. They are discussed as to their incidence location, diagnosis, treatment, and prognosis. A comparison of the benign and malignant tumors of these three series suggests two different trends of incidence in these rare lesions. The simultaneous, bilateral occurrence of a mucoepidermoid carcinoma of both submaxillary glands is described for what appears to be the first time.

Acknowledgments

Dr Catherine G Goetz, Associate Professor of Pathology advised on pathologic interpretation of the specimens processed and diagnosed by the Department of Pathology J G Brunson, M.D Professor and Chairman. Radiology studies by the Department of Radiology R. D Sloan, M.D Professor and Chairman. Photographic work by Mr J H. Dickson, Chief of Medical Illustrations. Externs William M. Aden and William K. Austin gave technical assistance. Charlene B Stephens, Ph.D helped with the preparation of manuscript.

6. Bardwil, J M Reynolds, C. T Ibanez, M. L., and Luna, M. A. Report of One Hundred Tu-

ion on the hard palate (Fig. 12) indicated lignant melanoma. The patient had had no ight loss.

Examination showed a mass (3 × 3 cm) in left neck over the carotid bifurcation ere was a black, ulcerated lesion (2 × 3 cm) r the hard palate He also had a papillatous lesion which filled the right nasal ity arising from the right middle turbinate. us x ray films showed massive clouding of right antrum and ethmoids. Liver scan g bone survey and brain scan were nor l. The chest x ray films were normal at t time. Biopsy of the nasal lesion showed enign squamous papilloma. Exploration of the right maxillary sinus through a Caldwell-Luc approach explained its mucosal proliferation as the result of chronic sinusitis. The palatal lesion was removed by the Plastic Surgery Service by wide excision of the hard palate and the entire alveolar ridge of the maxilla. At the same time we removed the medial wall of the right antrum with the attached papilloma. A left radical neck dissection was also done. A temporary maxillary prosthesis was inserted at the time of surgery

Subsequently the patient developed a pulmonary mass. He was alive with metastasis six months postoperatively at the time of this writing.

Discussion

ce its organization in 1963 the Division Otolaryngology of the Department of Sur y at the University of Mississippi Medical iter has admitted almost 10 000 patients the ENT clinic During these seven years, rare benign and malignant tumors of head neck have been seen and reported in a es of three papers. The first series included rare tumors, both benign and malignant. second series recorded 15 rare benign tu rs. This third series presents 15 rare ma ant tumors of the head and neck.

t was pointed out in the first two series of tumors that there was an unusually high portion of the cases occurring in the Negro (26 of 29) This could not be explained. was suggested to be of genetic influence present series of malignant tumors re ts an almost equal distribution in the icasian and Negro races. As expected the ignant tumors occurred in an older age up when compared with the benign tu rs.

he pathologic classification of these 15 tumors is as follows one squamous cell cinoma (septum) two malignant melano (septum and hard palate) two malignant mixed tumors (septum and submaxillary gland) one angiosarcoma of the maxillary and ethmoid sinuses two adenoid cystic carcinomas (nasopharynx and ear canal) one adenocarcinoma (parotid gland) one carcinoma of a minor salivary gland (ventricular fold in the larynx) one bilateral simultaneous, mucoepidermoid carcinoma of submaxillary glands, one rhabdomyosarcoma of the ethmoids, antrum and orbit one mucoepidermoid carcinoma of the parotid gland one ceruminoma of the ear canal and one papillary adenocarcinoma of the tongue Nine tumors occurred in males and six in females. Seven occurred in the Caucasian race and eight in the Negro race The average age was nearly 49 years.

When the three series are combined, as in Table 3 the trends encountered in the discussions of the two first series seem to emerge again albeit with a further modification. The three series are compared best by examining the benign and malignant lesions separately The following trends are seen to emerge the 24 benign rare tumors seem to predominate among the female (15 9), the Negro (22 2) and the younger age groups (17 7) The 20 malignant tumors seem to predominate

Introduction

Although there is considerable information about how the human body compensates for cold exposure and much has been written regarding the thermal homeostasis of man, very little is known about the effects of cold air temperature on the human auditory system. Carco (1952) summarized the existing literature in this area. The type of hearing loss he reported on—cases where rapid, sudden, and permanent deafness (unilateral or bilateral) occurred following cold exposures of varying durations and severity—was referred to as a cochlear block. The problem was sometimes noted to be accompanied by tinnitus of low pitch and or vestibular disturbances. Carco offered a variety of theories as to the physiology surrounding these observed severe sensorineural hearing losses as well as an interesting hypothesis to explain the selectivity of the effect of cold air exposure on hearing. He suggested that this may be based on a pre disposition determined by a variety of physical factors

Based on studies with laboratory animals there is also some evidence to suggest that extreme cold does have an effect on the cochlea and on hearing. This has been demonstrated both by altering body temperature and by directly changing the temperature in the cochlea. Kahana, Rosenblith, and Galambos (1950), using hamsters, and Gulick and Cutt (1960) using guinea pigs, demonstrated that the magnitude of the cochlear response was reduced when body temperature was reduced. Patterson et al (1968), using turtles, and Chambers and Loccina (1956), with a cat, obtained similar results when they locally reduced cochlear temperature without affecting the animals overall body temperature.

When specific human muscle tissue is exposed to cold, its activity is demonstrably diminished due to the generalized stiffness of the muscle (which is associated with the constriction of arteries, veins, and capillaries and the resultant general reduction of blood supply to the muscles involved). The tensor tympani and stapedius muscles would presumably respond similarly to chilling, the end result being that neither the tympanic membrane nor the auditory ossicles would move as freely as in the normal state. In addition, it is possible that the tympanic membrane might stiffen as a direct reaction to becoming chilled (reduced blood supply etc.). Also, the cold air may reach and affect the action of the tympanic membrane directly (via the external auditory meatus) and/or the middle ear muscles indirectly (through the venal blood supply and the mucosal lining of the nasopharynx).

It should be noted that head temperature (measured at the back of the nasal cavity and the interior of the ear) may not correlate well with body core temperature. Benzinger (1963) believed that this was possibly due to the passing of cooler blood returning from the ear lobe and surrounding area. The cooled blood in the descending veins would be adjacent to some of the ascending arteries which supply the tympanic membrane.

This resulting increased stiffness might be expected to affect the impedance characteristics of the middle ear along with the air conduction hearing thresholds. Based on the

Introduction

Although there is considerable information about how the human body compensates for cold exposure and much has been written regarding the thermal homeostasis of man, very little is known about the effects of cold air temperature on the human auditory system. Carco (1952) summarized the existing literature in this area. The type of hearing loss he reported on—cases where rapid, sudden, and permanent deafness (unilateral or bilateral) occurred following cold exposures of varying durations and severity—was referred to as a cochlear block. The problem was sometimes noted to be accompanied by tinnitus of low pitch and or vestibular disturbances. Carco offered a variety of theories as to the physiology surrounding these observed severe sensorineural hearing losses as well as an interesting hypothesis to explain the selectivity of the effect of cold air exposure on hearing. He suggested that this may be based on a predisposition determined by a variety of physical factors.

Based on studies with laboratory animals, there is also some evidence to suggest that extreme cold does have an effect on the cochlea and on hearing. This has been demonstrated both by altering body temperature and by directly changing the temperature in the cochlea. Kahana, Rosenblith, and Galambos (1950), using hamsters, and Gulick and Cutt (1960), using guinea pigs, demonstrated that the magnitude of the cochlear response was reduced when body temperature was reduced. Patterson et al. (1968), using turtles and Chambers and Lucchina (1956), with a cat, obtained similar results when they locally reduced cochlear temperature without affecting the animals overall body temperature.

When specific human muscle tissue is exposed to cold, its activity is demonstrably diminished due to the generalized stiffness of the muscle (which is associated with the constriction of arteries, veins, and capillaries and the resultant general reduction of blood supply to the muscles involved). The tensor tympani and stapedius muscles would presumably respond similarly to chilling, the end result being that neither the tympanic membrane nor the auditory ossicles would move as freely as in the normal state. In addition, it is possible that the tympanic membrane might stiffen as a direct reaction to becoming chilled (reduced blood supply, etc.). Also, the cold air may reach and affect the action of the tympanic membrane directly (via the external auditory meatus) and/or the middle ear muscles indirectly (through the venal blood supply and the mucosal lining of the nasopharynx).

It should be noted that head temperature (measured at the back of the nasal cavity and the interior of the ear) may not correlate well with body core temperature. Benzinger (1963) believed that this was possibly due to the passing of cooler blood returning from the ear lobe and surrounding area. The cooled blood in the descending veins would be adjacent to some of the ascending arteries which supply the tympanic membrane.

This resulting increased stiffness might be expected to affect the impedance characteristics of the middle ear along with the air conduction hearing thresholds. Based on the

research reviewed one could conclude that bone-conduction thresholds might also be affected if the cold air reached the cochlea. If the persons involved were warmly dressed as they normally would be when out of doors in cold weather the cold could only be passed to the inner ear through the middle ear (local cooling) since overall body core temperature would not be affected.

Empirical observations made earlier in our laboratory suggested that when normal hearing human subjects spent approximately 15 min out of doors in cold weather immediately prior to pure tone audiometric testing a conductive type stiffness tilt was observed instead of the expected normal audiogram. In most audiology clinics audiometric testing begins very shortly after the client arrives at the testing suite It is not unusual for clients who are warmly dressed but with their heads exposed to spend ten or fifteen minutes out of doors in temperatures below 0 F

Purposes of the Study

The primary purpose of this study was to determine the effects of extremely cold air temperatures on the human peripheral auditory system Assuming cold exposure takes place immediately before a person is tested, the specific questions asked were What effects will this exposure have on pure-tone thresholds, middle ear impedance and tympanic temperature?

A second function was to check the reliability of the test results obtained following the first 20 min exposure The third purpose was to determine the critical length of exposure (to −7 F) necessary before air-conduction thresholds are affected. The final purpose was to examine the recovery from the effects found.

Experiment I
Effects of the Initial Twenty Minute Exposure

METHOD

Forty-six college students with normal hearing and good general health were selected to serve as subjects. They were chosen on the basis of age (between 17 and 26 years) sex (approximately an equal number of males and females) and body build (only subjects judged to be of approximately average height and weight were used) In addition each subject's ears were inspected by an otologist to determine that the tympanic membranes were intact and healthy and to rule out any subjects whose external auditory canals were not of normal size, configuration and angle of inclination. Lastly whenever necessary the ears were cleaned of wax and/or other material

Pre- and post-exposure pure tone air and bone-conduction thresholds, acoustic impedance readings and tympanic temperature measurements were made in an empty and quiet but not sound-treated room located in the Michigan State University Food Stores building. Ambient noise levels in this room were 65 dB (C Scale) and 43 dB (A Scale) as measured with a sound level meter (Bruel and Kjær type 1613) employing a one inch sound field condenser microphone (Bruel and

Kjær type 4131). The noise levels were felt to be sufficiently low so as not to seriously interfere with pure-tone air-conduction threshold measurement (Cox, 1955). However it was necessary to use ear muffs (American Optical Company Model 1200) in order to obtain bone-conduction threshold measurements from the normal listeners.

For the cold exposures the subjects were placed in a large (120 feet by 120 feet) commercial type freezer located across a hallway from the testing room. The temperature in the freezer ranged from −3 F to −10 F during the course of the investigation and averaged −7.7 F. The doors to the freezer can be electrically or manually operated both from within and from without.

The subjects were instructed to eat nothing following lunch on the day they were to participate in the research. Immediately upon their arrival they were provided with a donut and a glass of milk and then waited 30 min to one hour before testing began. In this way an attempt was made to rule out differences in body metabolism as a complicating factor.

Each of the initial group of 46 subjects had their pure-tone air-conduction thresholds determined in both ears at octave intervals from 125 Hz through 8000 Hz using a portable audiometer (Beltone, Model 12 C) with TDH 39 10z earphones mounted in MX 41/AR cushions. This audiometer was calibrated to ISO 1964 standards. Attenuator linearity permitted testing in 2 dB steps. A 20 dB attenuation pad was inserted in one air-conduction line and in the bone-conduction circuit. American Optical Company ear muffs were used in measuring occluded bone-conduction thresholds. The bone-conduction oscillator used was a Radioear B 70 A white dot.

The pure-tone air-conduction system was calibrated weekly during the course of the investigation using an artificial ear assembly (Bruel and Kjær type 4152) employing a condenser microphone (Bruel and Kjær type 4132) with the associated sound level meter (Bruel and Kjær type 2203) and octave band filter network (Bruel and Kjær type 1613). The bone-conduction system was calibrated at the beginning of the research and again at its conclusion in the standard manner using an artificial mastoid (Beltone Model M5A) and was found to be satisfactory.

Because of the high ambient noise level in the test environment, conditions were not ideal for bone-conduction testing. It was desireable, nevertheless, to obtain the most sensitive and reliable bone-conduction thresholds possible under these conditions. Therefore, bone-conduction thresholds were measured without masking at octave intervals from 250 Hz through 4000 Hz using a forehead oscillator placement and with the ears occluded. Occlusion of the ears in normal subjects results in enhanced bone-conduction sensitivity particularly in the low frequencies (Naunton, 1957). Masking was not used in order to avoid the central masking phenomenon which produces an adverse effect on sensitivity of about 5 dB (Dirks, 1964). It was assumed that the bone-conduction responses were consistently elicited from the better ear (since masking was not used) and that, since both ears were exposed to the cold, they would both be affected in the same way. Forehead oscillator placement was used because it has been demonstrated to yield more reliable thresholds than mastoid placement (Dirks, 1964).

Pure-tone testing was carried out employing the Hughson–Westlake ascending technique as described by Carhart and Jerger (1959) with the exception that thresholds were measured in two decibel steps.

Following the first air-conduction threshold testing, the better ear was identified as the test ear. Air-conduction thresholds were obtained a second time in this ear. After a 20 min break, air-conduction thresholds were obtained a third time in the test ear. The bone conduction threshold testing was also done at this time. This provided pre-exposure thresholds and eliminated the complication of having thresholds improve with practice and

research reviewed, one could conclude that bone-conduction thresholds might also be affected if the cold air reached the cochlea. If the persons involved were warmly dressed, as they normally would be when out of doors in cold weather the cold could only be passed to the inner ear through the middle ear (local cooling) since overall body core temperature would not be affected

Empirical observations made earlier in our laboratory suggested that when normal hearing human subjects spent approximately 15 min out of doors in cold weather immediately prior to pure tone audiometric testing a conductive type stiffness tilt was observed instead of the expected normal audiogram. In most audiology clinics, audiometric testing begins very shortly after the client arrives at the testing suite. It is not unusual for clients who are warmly dressed but with their heads exposed to spend ten or fifteen minutes out of doors in temperatures below 0 F

Purposes of the Study

The primary purpose of this study was to determine the effects of extremely cold air temperatures on the human peripheral auditory system. Assuming cold exposure takes place immediately before a person is tested the specific questions asked were What effects will this exposure have on pure tone thresholds, middle ear impedance and tympanic temperature?

A second function was to check the reliability of the test results obtained following the first 20 min exposure The third purpose was to determine the critical length of exposure (to −7 F) necessary before air-conduction thresholds are affected. The final purpose was to examine the recovery from the effects found.

Experiment I
Effects of the Initial Twenty Minute Exposure

METHOD

Forty six college students with normal hearing and good general health were selected to serve as subjects. They were chosen on the basis of age (between 17 and 26 years) sex (approximately an equal number of males and females) and body build (only subjects judged to be of approximately average height and weight were used) In addition each subject's ears were inspected by an otologist to determine that the tympanic membranes were intact and healthy and to rule out any subjects whose external auditory canals were not of normal size, configuration and angle of inclination. Lastly whenever necessary the ears were cleaned of wax and/or other material.

Pre- and post-exposure pure tone air and bone-conduction thresholds, acoustic impedance readings and tympanic temperature measurements were made in an empty and quiet but not sound-treated room located in the Michigan State University Food Stores building Ambient noise levels in this room were 65 dB (C Scale) and 43 dB (A Scale) as measured with a sound level meter (Bruel and Kjær type 1613) employing a one inch sound field condenser microphone (Bruel and

Acoustic impedance in the plane of the ear drum is based upon the following formula.

$$Z_e = \frac{Z_1 \times Z_2}{Z - Z_2}$$

where Z is the point of minimum compliance of the middle ear system and approximately represents the actual canal volume and Z_2 is the point of maximum compliance of the middle ear system.

A measurement of middle ear pressure was noted for 11 subjects and, in five cases, the intra-aural stapedius muscle reflex threshold to a 250 Hz stimulus was measured. (This frequency was chosen because it was within the range of frequencies affected by the cold exposure.) Compliance readings at a variety of pressure settings were taken for 15 subjects in order to determine the compliance of the ear drum under varying canal pressure conditions. The headset was not removed and sensitivity and pump controls were returned to zero. The pressure in the canal was then raised to + 200 mm and the sensitivity control set to position 1. The compliance control was adjusted so that the balance meter reading was 10. The canal pressure was then reduced in 40 mm steps and the balance meter readings noted at each of the pressure settings tested. + 160, + 120, + 80, + 40, 0, − 40, − 80, − 120, − 160, and − 200 mm water pressure.

Subjects were allowed to dress as warmly as desired (leaving the head and ears exposed) before entering the freezer for 20 min. They were instructed not to run, jog, exercise, or engage in any type of strenuous activity.

The order of tests was: air-conduction thresholds, bone-conduction thresholds, impedance (when measured), and temperature (when measured). The same test order was followed during the post-exposure session. When hearing thresholds shifted, the subjects were not allowed to lea e the building until the affected thresholds had returned to pre-exposure levels. Generally a threshold check was made one hour following the conclusion of the cold exposure. If thresholds had not then returned to pre-exposure levels, another check was made 15 or 20 min later. In all cases thresholds had returned to normal within 80 min following the conclusion of the cold exposure.

RESULTS

Table I shows the means and standard deviations for the shifts in occluded bone-conduction thresholds and the significance levels of the mean shifts (from pre-exposure to post exposure readings) for 46 subjects following a 20 min cold exposure. The primary statistic shown throughout the Results section is a one-way analysis of variance.

The mean shifts found by occluded bone-conduction testing following the cold exposure were extremely small (the largest mean shift being less than 1 dB) and none of the shifts differed significantly from zero ($P \geq 17$). In addition, no subject showed consistent bone-conduction threshold shifts following the cold exposure. It would appear then, that 20 min of cold exposure under these conditions does not measurably affect bone-conduction thresholds.

The means and standard deviations of the pre and postexposure air-conduction thresholds and the shifts in air-conduction thresholds plus the significance levels of the mean shifts for the total group of 46 subjects are shown in Tables II and III.

Table I. *Means, standard deviations and significance levels of mean shifts in occluded bone-conduction thresholds found for the 46 subjects following a 20 min cold exposure*

thereby possibly contaminate the results obtained following the cold exposure

For 37 of these subjects tympanic temperature was also determined prior to the cold exposure using a tympanic thermometer (Radiations Systems, Inc. Model no. 104382). This thermometer is battery operated. It is a small (13 × 9 × 7") portable (14 1/3 lbs) cabinet from which a six foot lead connects to interchangeable disposable probes or thermocouples which consist of constantan and copper wire embedded in thin polyethylene tubing The end of the wire is looped and the soldered junction is also embedded in the tubing. Thermocouple wires surrounded with polyethylene tubing facing the interior of the auditory canal with their free ends help to hold the probe in place against the tympanic membrane while the temperature measurement is being made. The use of a thermoelectric method (as opposed to thermistor measurements) requires amplification This is provided so that readings may be made to 1/100 C. Using this equipment tympanic temperature may be obtained within 15 sec at an accuracy of up to 0.2 C.

The thermocouple wires were inserted into the external canal until they reached the tympanic membrane. This point was determined in three ways. Tactually when the probe reached the drum membrane there was the distinct feeling of a sudden resistance to further insertion Secondly the subject usually reported a slight twinge when the probe touched the tympanic membrane Thirdly the highest temperature reading possible in the canal is on the drum membrane. Therefore a final check to correct placement was to slightly withdraw the probe If the probe was correctly placed originally the tympanic temperature dropped somewhat when the probe was withdrawn slightly Then it was replaced.

For some subjects a variety of impedance measurements were made using a Madsen Acoustic Bridge Model ZO 70. This bridge is composed of a pure-tone generator which produces a probe tone of 220 Hz, a pressure system composed of a pump and an electromanometer and a section for acoustic impedance measurements. The pure-tone generator is connected to an earphone and a tube from the earphone conveys the 220 Hz tone to the probe unit (which is part of the headset) and then into the external auditory meatus. The meatus is sealed forming an air tight cavity Some of the acoustic energy is absorbed the remainder is reflected by the tympanic membrane and conveyed back to a microphone in the probe unit through a second tube. A third tube is connected to the probe unit from the pressure system which allows positive or negative air pressures to be applied to the external auditory canal. The sound pressure level in the canal may be varied (Madsen manual).

When the compliance control is adjusted to give a zero reading on the balance meter the sound pressure level in the canal is precisely 95 dB (When the microphone voltage equals 18 volts the voltage at the balance meter is zero since it has been perfectly balanced with the DC 18 volt supply provided by the bridge on the other side of the meter) With this equipment the reactance or compliance of the ear may be read on a scale in acoustic ohms or in cc and the impedance calculated in acoustic ohms. In addition it is possible to determine the presence or absence of the middle ear muscle reflexes, measure the compliance of the ear under a variety of air pressures and perform other impedance measurements.

The headset was fitted with a TDH 39 earphone and an eartip of suitable size was selected and fitted onto the probe The probe was inserted into the meatus and then checked to ascertain that an airtight seal had been achieved (by increasing the canal pressure to +200 mm water pressure and waiting a few seconds to observe on the pump control that the pressure had held steady). Measurement of acoustic impedance in the plane of the ear drum was made in 45 subjects according to the directions given in the Madsen manual

shifted downward by the cold exposure. Fig. 1 displays the pre- and post-exposure air-conduction thresholds for the shifter group. Fig. 2 presents the same data for the remaining 26 subjects classified as non-shifters. The threshold shifts found in the shifter group were greatest in the low frequencies (in the direction of poorer hearing), disappeared in the mid frequencies and became very slightly improved in the high frequencies. The non-shifters, on the other hand, showed virtually no threshold shifts at any frequency and the variation around zero appeared to have no pattern. The differences in the air-conduction shifts between the two groups were significant at 125 Hz, 250 Hz, and 500 Hz (at a level of 0.0005), whereas none of the pre-exposure thresholds were significantly different from those found for the total group. When the threshold shifts were correlated with pre-exposure thresholds at 125 Hz and 250 Hz, they were significantly related and there was a marginal correlation at 500 Hz. In all three cases the relationship was negative indicating that the better the original threshold at these frequencies, the greater the size of the threshold shift.

The ranges, means, and standard deviations

of the pre- and post-exposure tympanic temperature readings and shifts in tympanic temperature as well as the significance level of the mean shift is given in Table IV. The mean pre-exposure temperature was 98.00 F which agrees well with the figure reported by Ganong (1967) (98.10 F) for healthy young adults. The mean post-exposure temperature reading was 97.28 F showing a mean shift of −0.72 F. In no case did tympanic temperature rise following the cold exposure although in a few cases it was unchanged. There was a slight difference in the pre-exposure temperatures of the shifters and non-shifters.

In dB re 0 hearing level (ISO 1964).

The effect of the ambient noise level in the testing room can be seen on the low frequencies in Table II Since the high frequency thresholds are close to 0 dB hearing level, it seems reasonable that the low frequencies should also be near 0 dB hearing level. Thresholds appeared to be worsened by about 11 dB at 125 Hz, 15 dB at 250 Hz, 18 dB at 500 Hz, and 6 dB at 1000 Hz. This does not seem unreasonable given the ambient noise levels reported earlier Even with this level of "masking present however Table III shows that the cold exposure did affect the air conduction thresholds particularly in the lower frequencies (from 125 Hz through 500 Hz) following the 20 min cold exposure. Thresholds were very slightly improved (though not significantly so) in the higher frequencies (from 2000 Hz through 8000 Hz)

The mean air-conduction shift found was statistically significant at 125 250 500 and 1000 Hz. The mean threshold shifts found from 125 Hz through 1000 Hz were all in the direction of poorer hearing whereas at the higher frequencies the shifts, although not statistically significant, were all in the direction of slightly improved hearing. This type of audiometric curve, with depressed low frequency air-conduction thresholds, when accompanied by normal bone-conduction thresholds, is usually considered to be representative of increased stiffness in the mechanical action of the ear (Campbell, 1950)

An operational definition was established for determining which of these subjects should be classified as "shifters" in air-conduction thresholds following the cold exposure. It was decided that a subject would be classified as a shifter if two of the three low frequency thresholds (125 Hz, 250 Hz, and 500 Hz) shifted by +4 dB or more and the third shifted by at least +2 dB In this way 20 subjects (10 males and 10 females) were found to have air-conduction thresholds that were

In mm water pressure.
[b] *Difference between shifters and non-shifters is not* statistically significance ($P=0.25$).

The mean pre-exposure temperature for the shifters was 97 83 F and for non shifters was 98.15 F The mean temperature shift was virtually the same for both groups being −0 68 F for the shifters and −0 75 F for the non-shifters.

With regard to acoustic impedance Hood and Lamb (1969) reported a mean of 1565 ohms with a standard deviation of 593 and a range of 657 to 2964 ohms using a sample of 42 normal ears. Some of this variation was undoubtedly due to the depth of insertion of the eartip In order to test this notion two post-exposure impedance readings were made for five of the subjects once using an insertion done in the normal manner and once with the eartip inserted to the point at which the pre-exposure volume had been matched. The former shall be referred to as free impedance and the latter as controlled impedance The differences between controlled and free impedance readings for the five subjects were within normal test retest variability Hood and Lamb (1969) reported a mean test retest variation of 130 ohms with a range of 4 to 347 ohms. Measurements of acoustic impedance in the plane of the eardrum were made on 44 out of the 46 subjects free impedance measurements on 32 and controlled impedance measurements on 17 The mean pre-exposure impedance levels agree quite well with the Hood and Lamb data. All of the shifts in impedance were in a positive (stiffer) direction following the cold exposure regardless of whether the post-exposure measurements were controlled or free. The total amount of the shift found however following the exposure was not significant for either the controlled or the free impedance ($P=0.23$ and $P=0$ 12, respectively).

The 20 min exposure had no significant effect on overall acoustic impedance and differences between shifters and non shifters were small and not significant with regard to overall acoustic impedance This is probably because this measure is too gross for our purposes.

When middle ear pressure measurements were obtained pre and post-exposure on a random sample of subjects representative of the total group shifters and non shifters, some differences were found The measurement taken here is the amount of air pressure that must be added to the external auditory canal in order to reach the point at which the ear canal and middle ear pressures are equal and the eardrum is in the midline position In other words, it is the reading of the equivalent middle ear pressure. The ranges, means, and standard deviations of the pre and post exposure middle ear pressure readings and the shift in middle ear pressure following exposure and the significance of this shift is given in Table V for the total sample and for the shifters and non shifters.

Viewing the total group Table V reveals that there was a real difference in middle ear pressure from pre-exposure to post-exposure in that the cold exposure apparently caused the middle ear pressure to increase by more

than 10 mm water pressure. This shift in middle ear pressure is significant at the 0.001 level of confidence. However both the shifters and non-shifters showed this increase in middle ear pressure following exposure. Although the shifters showed a slightly larger increase, it was not statistically significantly different from the shift shown by the non-shifters. Prior to the exposure, however the shifters middle ear pressure was significantly lower than that of the non-shifters. The pre-exposure mean for the shifters (1.67 mm) was close to what would be considered the mean normal reading (0 mm) and well within the range reported by Hood and Lamb (1969) −5 mm to +5 mm. The non-shifters, on the other hand, had greater middle ear pressure (17.00 mm) prior to exposure. The implication is that the non-shifters ears were stiffer prior to exposure but then moved in the same direction as the shifters ears moved.

In addition, it is helpful to know the compliance readings at various pressure settings so that the relationship between pressure and compliance can be determined. In the present study the pressure was varied in 40 mm steps from +200 mm water pressure to −200 mm water pressure. The balance meter on the acoustic bridge was set at +10 for the condition of +200 mm water pressure and its readings then noted for each of the other conditions. The lower the balance meter readings, the more compliant the system would be. One would therefore expect, if one were to draw a curve using these points from +200 mm water pressure to −200 mm water pressure, to have the curve peak at 0 mm water pressure since this should be the point of greatest compliance in the normal ear. Fig. 3 displays the mean compliance readings (again using a random sample of the subjects) at each of the pressures tested for the total group (15 subjects) for the shifters (7 subjects) and non-shifters (8 subjects) in the pre and post exposure conditions.

Again differences in pre-exposure readings were found between the shifters and non-

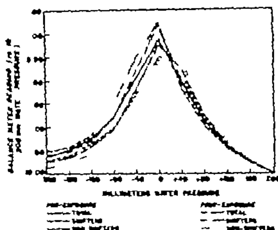

Fig. 3. Mean pre- and post-exposure compliance readings at each of the pressures tested for the total group, shifters and non-shifters.

shifters. From the pre-exposure curves in Fig. 3 it can be seen that, at most pressure levels the non-shifters ears were less compliant than the shifters ears. This agrees with the findings cited earlier. A difference appears to exist between the shifters and non-shifters' ears prior to the cold exposure. All of the various impedance measurements indicated that shifters had more compliant ears to start with. The implication is that the cold only affected hearing thresholds in ears with normal compliance. Threshold shifts did not occur in those ears that were already stiffer than normal (by about 15 mm water pressure) *prior* to the exposure. However both of the groups (shifters and non-shifters) compliance readings reacted similarly to the cold exposure. The compliance curve in both cases seems to have been shifted with the result that compliance under negative canal pressure conditions appears to be reduced following the cold exposure and slightly enhanced under positive canal pressure conditions. This is consistent with the previous finding concerning the change in middle ear pressure following the cold exposure. The implications of this finding will be discussed later. The post-exposure curves for the total group shifters and non-shifters appear to have been shifted to the

right by approximately 10 mm water pressure the change in middle ear pressure found following the cold exposure

The three types of impedance measurements discussed so far all resulted in the same conclusions 1) all of the subjects appeared to be affected in much the same way and to the same extent following the cold exposure and 2) the subjects whose hearing thresholds did not shift following the exposure had stiffer ears prior to exposure.

The last type of impedance measurement made was concerned with the intra-aural stapedius muscle reflex threshold to a stimulus of 250 Hz. The mean results were approximately the same for all of the groups both before and after the cold exposure and the level found agrees well with previous research. Jepsen (1963) reported mean thresholds of hearing and stapedius reflexes by frequency according to the age of the subjects. He found the reflex threshold for a stimulus of 250 Hz for 20 year old subjects to be approximately 85 dB above threshold (and normal threshold at 250 Hz to be 0 dB) If one assumes that the threshold for the groups of subjects tested here would have been approximately 0 dB if they had been tested under ordinary audiometric testing conditions, i.e. in a sound-treated room, one would conclude that the muscle reflex thresholds found in this study agree closely with those found by Jepsen (82 dB as compared with 85 dB). The results imply that the subjects had normal hearing at 250 Hz, and that differences in middle ear pressure and degree of stiffness of the system had no effect on the intra aural muscle reflex threshold when a 250 Hz stimulus was used.

Experiment II
Varying Exposure Durations and Recovery

The purpose of the second experiment was threefold 1) to check the reliability of the effects of the previous 20 min exposure on pure tone thresholds, middle-ear impedance and tympanic temperature 2) determine what the critical length of exposure is before hearing thresholds are affected and 3) allow for recovery tracking Nine of the 20 normal hearing young adult subjects who had been previously classified as shifters returned for three additional testing sessions with at least 24 hours but not more than four days between each session These sessions differed in the length of cold exposure—one being of five minutes duration one of ten minutes duration and the third a repeat of the 20 min duration The exposures are identified as follows Exposure 1 initial 20 min exposure reported in Experiment I Exposure 2, second 20 min exposure Exposure 3 10 min Exposure 4 5 min At each of these latter three testing sessions all procedures were followed exactly as described in Experiment I above with the exception that bone-conduction thresholds were not obtained. The order of the three exposures was rotated.

In addition in order to examine recovery patterns, pure tone air-conduction thresholds were obtained in the test ear for each subject immediately following the cold exposure and then every 20 min until the thresholds returned to normal and became stable (Thresholds were considered stable when measured no less than two times at 20 min intervals with no changes observed ±2 dB) Finally tympanic temperature and all impedance measurements were made once more for each subject as soon as air-conduction thresholds had stabilized at pre-exposure levels. The purpose of this final check was to determine if impedance readings and tympanic temperature had also returned to normal (pre-ex

[a] In dB re pre-exposure thresholds.

posure) levels when air-conduction thresholds had done so.

RESULTS

Analysis of [v]ariance showed that the pre-exposure air-conduction thresholds for each of the three exposures, 20 min, 10 min and 5 min did not differ significantly ($P \geq 0.15$) from one exposure to another at any frequency. The means and standard deviations of the threshold shifts for each of the three exposure durations is presented in Table VI. The length of the exposure duration has a statistically significant effect on the size of the threshold shift at 125 Hz, 250 Hz, and approaches significance at 500 Hz and 1000 Hz. By 2000 Hz the length of exposure no longer appears to have any significant effect on the size of the threshold shift. It appears that there is a real difference in threshold shift particularly in the lowest frequencies, depending on the length of exposure. Thus, the longer the exposure the greater was the low frequency air-conduction threshold shift.

The mean pre-exposure tympanic temperature (97.44 F) was slightly below that found for the total group of 46 subjects (98.0 F), but agreed quite well with the mean pre-exposure temperature found for the shifters (97.83 F), the group from which the nine were drawn. The pre-exposure differences from Exposure 1 to Exposure 2, 3 and 4 were not significantly different. However the temperature shift found following the second 20 min exposure was larger (−1.46 F) than that found for the shifters following the first 20 min exposure (−0.68 F). The temperature shifts found following the 10 and 5 min exposures were similar to each other and to the level found originally following the 20 min exposure. Exposure of the ears, then, for even 5 min to a temperature of approximately −7 F affects the temperature on the tympanic membrane. There appears to be no distinct relationship between the length of exposure and the size of the shift. The temperature shifts following all of the exposure durations were approximately the same with the exception of the second 20 min exposure duration.

As in the case of the 46 subjects, none of the differences found in pre- or post-exposure acoustic impedance were significant, nor were the shifts found significant. Either there was no change in absolute impedance following the cold exposure or this measure is too gross for the small effects being considered here. In viewing middle ear pressures, however differences do appear as they did among the group of 46 subjects in Experiment I. Except for the 10 min exposure, a real difference in middle ear pressure of about +10 mm was found again following the cold exposures. Provided that the cold exposure is at least 5 min, the length of the exposure probably has no effect on the size of the shift. The

peculiar shift found following the 10 min exposure is difficult to explain but is most likely due to a couple of subjects who reacted peculiarly to this particular exposure and thus represents extreme values.

There were no significant differences found between the pre-exposure compliance measurements prior to any of the three exposure sessions. There were, however significant differences found in the compliance shifts following each of the three exposure durations for the nine subjects. The shifts became significantly different according to the length of the exposure under positive canal pressures only The pre and post-exposure curves for the 20 and 5 min exposures are very similar and like the pre and post-compliance curves found for the total group of subjects. The 10 min exposure compliance curves, however are different from the others. The shift in direction is directly related to the shift in direction found in the middle ear pressure for this exposure duration. Whatever caused the pressure changes must have caused the compliance changes also and cannot be explained. These results are out of keeping with the air conduction results obtained. (The air-conduction shifts found following the 10 min exposure were intermediate between the 20 and 5 min exposures.)

The differences in pre and post-exposure compliance readings for the 20 min and 5 min exposure durations were small but all in the direction of greater stiffness following the 20 min exposure at both negative and positive pressures. The compliance curve then as was the case in the 46 subjects, appears to be the most sensitive measure of the effect of the cold exposure on the ear other than the shift in hearing threshold. The variation in length of the cold exposure seems to affect the extent of the shift in compliance namely the longer the exposure duration the greater the stiffness of the middle ear

The last measure of acoustic impedance examined was the intra aural muscle reflex threshold to a stimulus of 250 Hz. The pre-exposure stapedius muscle reflex levels were normal and very similar to those found for the total group of shifters (82.5 dB) The difference in intra aural stapedius muscle reflex thresholds following the three exposures were not significant. Again, the implication is that the intra-aural muscle reflex threshold to a stimulus of 250 Hz is not affected by the cold exposure and not related to shifts in compliance of the ear or to air-conduction threshold shifts.

Pure tone air-conduction thresholds were obtained for each of the nine subjects immediately following each of the three exposures and then at 20 min intervals until the thresholds returned to normal Table VII presents the mean post-exposure air-conduction thresholds by frequency at 20 min intervals following the 20 min exposure duration

Recovery is defined as the point in time when thresholds returned to normal (pre exposure) levels (± 2 dB) and does not include the final or stabilization check thresholds. Recovery appears to proceed rather systematically from T to T_{60} and is then essentially complete within 60 min following the conclusion of the exposure. Of the nine subjects tested one took only 20 min for full recovery one took 40 min, six took 60 mm, and one took 80 min.

Individual recovery curves for the frequencies 125 Hz, 250 Hz, and 500 Hz are presented in Fig. 4 for the nine subjects following the 20 min exposure. As can be seen, the three recovery curves are quite similar (with the exception of 250 Hz at T_{40}) and the rate is fairly constant. The point of complete recovery should ideally be the time at which the recovery curve reaches the 0 point. However there is a certain amount of test-retest variability in threshold measurement and taking this into account, it appears that the air conduction threshold shift at 125 Hz, 250 Hz, and 500 Hz following a cold exposure of 20 min has fully recovered within one hour after the exposure

Full recovery following the 10 min exposure took place within 40 min following the conclusion of the exposure. Of the nine subjects, seven showed full recovery after 40 min,

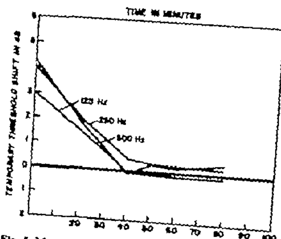

Fig. 5. Mean recovery curves at 125 250, and 500 Hz following the 10 min exposure duration (N = 9).

one following 60 min, and one subject did not show any threshold shift at all. The individual recovery curves for the frequencies 125 Hz, 250 Hz, and 500 Hz following the 10 min exposure duration are shown in Fig. 5 Although the starting points are somewhat lower than in Fig. 4 (the threshold shift following the 20 min exposure), the recovery curves are again quite similar in rate as well as pattern.

Recovery following a 5 min exposure cannot be examined, since there were no significant threshold shifts following this length of exposure. It appears that the pattern of recovery from temporary threshold shifts caused by cold exposure are similar for varying lengths of exposure but that the length of the exposure determines the time required for recovery

The tympanic temperature readings returned to pre-exposure levels within the amount of time needed for the air-conduction thresholds to recover

The differences between the pre-exposure and final acoustic impedance measurements were also very small. The mean difference from pre-exposure to final reading was −2.78 ohms for the 20 min exposure. Middle ear pressure, on the other hand, did not completely return to pre-exposure levels by the

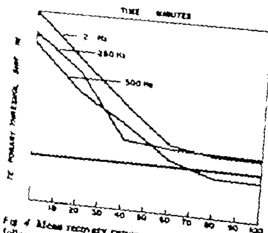

Fig. 4. Mean recovery curves at 125 250, and 500 Hz following the 20 min exposure duration (N = 9).

time of the final measurement. The mean middle ear pressure reading prior to the 20 min exposure was −7 1 mm water pressure, and by the time of the final check it was +1 2 mm water pressure The question exists as to whether some of this difference is due to test retest variability or whether perhaps the middle ear pressure had not fully recovered by the time the air-conduction thresholds had done so

There were differences between the pre-exposure and final compliance readings also The ears apparently were somewhat more compliant at all pressures at the time of the final check but it should be noted that the differences are approximately equal at all of the pressure levels. The type of shift in compliance readings found following both 20 min exposures, however was completely gone by the time of the final compliance check. Finally the acoustic reflex was unaffected by the cold exposure and remained unchanged at the time of the final testing.

Thus, it appears that the effect of cold exposure on impedance is also temporary and that the shifts found essentially recover within the time necessary for the air-conduction thresholds to recover

Conclusions

Cold exposure as described herein appears to have a specific effect on low frequency pure-tone air-conduction thresholds, middle ear impedance, and tympanic temperature When the test conditions were replicated, the same results, in general, were obtained. Further it was found that 10 min exposure was sufficient to affect the hearing mechanism but that 5 min exposure was not. The critical exposure duration then is somewhere between 5 and 10 min.

The recovery curves following the 20 and 10 min exposures were similar in rate and pattern Recovery from the 20 min exposure took approximately one hour whereas recovery from the 10 min exposure took about 40 min

Discussion

Five possible explanations may account for the threshold shifts found. These are 1) the shift in threshold is due to the fact that the cold affects the entire body not only the ear resulting in generalized chilling shivering etc. 2) there is a direct effect of the cold air on the action of the inner ear 3) there is a direct effect of the cold air on the action of the middle ear muscles, tendons, and ligaments 4) the threshold shifts are due to a disequilibrium in air pressure between the external canal and the middle ear following the cold exposure and 5) there is a direct effect of the cold air on the action of the tympanic membrane Although it is unlikely that any single explanation will account for the effects found each will be considered individually

In order to determine what effect generalized body chilling might have on hearing thresholds, three subjects who were lightly dressed were exposed for longer periods of time to somewhat higher temperatures, 35 to 40 F Each of these subjects remained in this environment for 30 to 40 min or until they were thoroughly chilled as evidenced by shivering and horripilation None of these three

subjects showed any shift in hearing following this exposure. The subjects in the present study were, of course, warmly dressed, but with their heads exposed the possibility existed that the shift in hearing thesholds might have been caused by generalized body cooling or by muscular contractions throughout the body rather than by specific cooling of the head only. The pilot study referred to above demonstrated that thoroughly chilling subjects does not have any effect on hearing thresholds. This does not rule out the specific effect of cold on the ear itself however.

As discussed in the review of the literature, Kahana, Rosenblith, and Galambos (1950) and Gulick and Cutt (1960) demonstrated that when body temperature was reduced the magnitude of the cochlear response was likewise reduced, and Gulick and Cutt also reported concomitant hearing losses. But, it is also well established that the inner ear can be affected by cold air even when body temperature is unchanged. This, of course, is what occurs in caloric testing, whether cold water or cold air is employed as the stimulus. The question, therefore of whether the threshold shifts found following the cold exposure might be due to changes in the inner ear is certainly a pertinent one.

One would expect, however that were these threshold shifts due to changes in the inner ear the bone-conduction thresholds would also have been affected. Since bone-conduction thresholds remained essentially the same following the cold exposure, one must conclude that the shifts in air-conduction thresholds following the cold exposure were probably due to factors other than changes in the response of the inner ear. The conclusion must be made cautiously since it is possible that given longer exposure durations or lower temperatures, an effect on bone-conduction thresholds might occur as Carco (1952) reports. This will be discussed in more detail later in conjunction with middle ear pressure.

The possibility needs to be explored that the middle ear became so cold following the exposure that the tensor tympani and stapedius muscles contracted, thereby creating the air-conduction loss. Since no threshold shift was found when the pilot study subjects were put into the cold room lightly dressed and were thoroughly chilled and shivering, it seems unlikely that the middle ear muscle contractions can be credited with the threshold shifts found following the exposure under the present conditions. Also, even if muscular contractions had occurred, it is improbable that duration of contraction would have extended for up to an hour post exposure, the length of time necessary for full recovery following a 20 min exposure. It is possible however that there was some contraction of the tendons and ligaments in the middle ear most particularly the tendons of the stapedius muscle which might have contributed in part to the hearing threshold shifts found and to the overall increased impedance of the middle ear system.

Smith (1943) mechanically fixated the stapes in cats and measured changes in the cochlear responses for air and bone-conduction which resulted. The degree of stapes fixation varied according to the amount of tension placed on it. Hearing losses found were greatest in the low frequencies by air-conduction the mean losses ranging between 30 and 40 dB, whereas by bone-conduction the losses ranged only between 9 and 10 dB. If there were some cooling of the tendons of the stapedius muscle, one might expect to get similar results, i.e. hearing loss in the low frequencies by air-conduction and little or no hearing loss by bone-conduction.

The air-conduction losses found here, however were much smaller than those found by Smith, implying that if increased tension in the stapedial muscle was responsible for the threshold shifts found in this study the increase in tension must have been quite small.

The greatest effect of the cold air exposure would be expected in the outer ear canal. Pre and post-exposure otoscopic examinations were made by an otolaryngologist on a sample

time of the final measurement. The mean middle ear pressure reading prior to the 20 min exposure was −7 1 mm water pressure and by the time of the final check it was +1 2 mm water pressure. The question exists as to whether some of this difference is due to test retest variability or whether perhaps the middle ear pressure had not fully recovered by the time the air-conduction thresholds had done so

There were differences between the pre exposure and final compliance readings also The ears apparently were somewhat more compliant at all pressures at the time of the final check but it should be noted that the differences are approximately equal at all of the pressure levels. The type of shift in compliance readings found following both 20 min exposures, however was completely gone by the time of the final compliance check. Finally the acoustic reflex was unaffected by the cold exposure and remained unchanged at the time of the final testing

Thus, it appears that the effect of cold exposure on impedance is also temporary and that the shifts found essentially recover within the time necessary for the air-conduction thresholds to recover

Conclusions

Cold exposure as described herein appears to have a specific effect on low frequency pure tone air-conduction thresholds, middle ear impedance and tympanic temperature When the test conditions were replicated the same results, in general were obtained Further it was found that 10 min exposure was sufficient to affect the hearing mechanism but that 5 min exposure was not. The critical exposure duration then is somewhere between 5 and 10 min

The recovery curves following the 20 and 10 min exposures were similar in rate and pattern Recovery from the 20 min exposure took approximately one hour whereas recovery from the 10 min exposure took about 40 min

Discussion

Five possible explanations may account for the threshold shifts found. These are 1) the shift in threshold is due to the fact that the cold affects the entire body not only the ear resulting in generalized chilling shivering etc. 2) there is a direct effect of the cold air on the action of the inner ear 3) there is a direct effect of the cold air on the action of the middle ear muscles tendons, and ligaments 4) the threshold shifts are due to a disequilibrium in air pressure between the external canal and the middle ear following the cold exposure and 5) there is a direct effect of the cold air on the action of the tympanic membrane Although it is unlikely that any single explanation will account for the effects found, each will be considered individually

In order to determine what effect generalized body chilling might have on hearing thresholds, three subjects who were lightly dressed were exposed for longer periods of time to somewhat higher temperatures, 35 to 40 F Each of these subjects remained in this environment for 30 to 40 min or until they were thoroughly chilled as evidenced by shivering and horripilation None of these three

Using the Valsalva procedure Loch (1942) found that a moderate increase in middle ear pressure reduced hearing acuity in the lower frequencies by approximately 10 dB. Wever and Lawrence (1954) believed that these effects were probably due to altered tension of the tympanic membrane. They further suggested, however that should the pressure in the middle ear be sufficient, the effect might continue on into the inner ear One would suspect that in the present investigation the pressure build-up in the middle ear was not sufficient to affect the inner ear since the bone-conduction thresholds were unchanged. Based on the specific effects of both positive and negative pressures on air-conduction thresholds, they concluded that both the damping and stiffness of the tympanic membrane were affected, the damping being responsible for the reduction in sensitivity and the stiffness causing the low tones to be affected primarily

The possibility exists that the tympanic membrane is affected by the cold air reaching it through the external auditory canal. If the tympanic membrane were to be cooled, the result would be increased stiffness in its action. In order to demonstrate whether or not the tympanic membrane actually is cooled by the cold exposure, each individual's temperature was taken on the tympanic membrane both before and after each exposure session. The temperature of the tympanic membrane was decreased by approximately 0.7 F following the cold exposure. It is unknown to what degree the membrane's action was affected, but, should the tympanic membrane be stiffened as a result of the cooling, the change in impedance would result in depressed low frequency air-conduction thresholds. When the pure-tone air-conduction thresholds had returned to normal so had tympanic temperature This must certainly be considered as part of the explanation for the threshold shifts observed.

In conclusion, five possible explanations have been presented in order to account for the air-conduction threshold shifts found. The first, that the effects seen were due to generalized body chilling and/or overall muscular contractions, seems unlikely The second, that the effects were due to changes in the action of the inner ear seems unlikely also. However it is felt that this could be a factor were the exposure longer or the cold more extreme. The most likely explanation for the threshold shifts found appears to be some combination of three physiological effects, namely 1) subtle changes in the action of the middle ear muscles, 2) increased air pressure in the middle ear and/or 3) a reduction in the vibratory capacity of the tympanic membrane.

The combination of one or more of these factors would result in an increase in the stiffness of the middle-ear system. This change in impedance of the system would be reflected in the post-exposure depressed low frequency pure-tone air-conduction, threshold shifts found. Since the type of audiogram obtained following the cold exposure is similar to that found in patients with adhesive otitis media and pre-clinical otosclerosis, care should be taken to determine how long a patient was out of doors in cold air temperatures immediately preceding an audiometric evaluation. Sufficient time should be allowed for threshold shifts caused by the cold air out doors to fully recover before pure-tone testing is begun to help insure valid pure tone test results and to aid in avoiding misdiagnoses of middle ear pathology

Finally this investigation provides further information regarding the effects of altering the normal physiological state of the human middle ear system.

of the subjects. He found the walls of the canal definitely cooled by the exposure, and the resultant stiffening of the canal walls to be very noticeable. It can be demonstrated by use of the tympanic thermometer that the tympanic membrane is also affected by the cold exposure. It does not seem unreasonable to further assume that the middle ear is somewhat cooler than normal also but undoubtedly not as cool as the external canal. Air of course, expands as temperature rises and should the temperature in the middle ear be warmer than that in the external auditory canal a disequilibrium in air pressure between the external canal and the middle ear cavity would result. Under ordinary circumstances, one would expect that this difference in air pressure would be equalized through the action of the eustachian tube. For a variety of reasons the eustachian tube may not have been capable of correcting these pressure differentials under the experimental conditions used in this investigation. First, a certain minimum amount of pressure difference is necessary to open the eustachian tube probably between 0.5 and 4 mm mercury (Ballenger 1969). The increase in air pressure in the middle ear found in this investigation i.e. approximately +10 mm of water pressure (10 mm water pressure is equal to 0.7 mm mercury) simply may not have been enough to blow open the eustachian tube. However it may have been enough to cause a slight change in the mechanical action of the middle ear

Secondly it was noted that many of the subjects emerged from the cold room with "sniffles. Scott-Brown (1965) and Boies (1957) also comment on temporary congestion, inflammation membrane swelling and nasal discharge as a result of chilling. This could certainly have reduced the patency of the eustachian tube as would happen in the case of a common cold. It is more difficult to equalize pressure between the middle ear and outer ear when there is mucosal congestion. In fact, the possibility exists that the patency of the eustachian tube may be the key factor that differentiated subjects who shifted from those who did not shift. Those subjects whose eustachian tubes remained most patent were perhaps more able to compensate for the disequilibrium in air pressure and therefore did not show the threshold shift whereas, those subjects who were not able to equalize the pressure between the middle and outer ear showed the threshold shift. This explanation agrees with our findings cited earlier: following the cold exposure the middle ear pressure had increased more in the shifters than in the non-shifters. Presumably the non-shifters were able to equalize the air-pressures in their external canals and middle ears, thereby maintaining normal impedance and normal air-conduction thresholds. The differences are small, however as is the number of subjects involved. More important perhaps is the fact that most of the subjects showed some increase in the middle ear pressure following the exposure. This shift in middle ear pressure following the cold exposure was significant at the 0.001 level of confidence.

It was noted previously that post-exposure compliance curves showed reduced compliance under negative canal pressure conditions and enhanced compliance under positive canal pressure conditions. If the middle ear pressure had indeed been somewhat increased and the tympanic membrane displaced outwards slightly this is exactly what one would expect to occur. Adding pressure to the external canal would help to bring the air pressure back into equilibrium and allow the tympanic membrane to come closer to its normal (mid-line) position, thereby reducing the stiffness (and increasing the compliance) of the system. Withdrawing air from the external canal creating a negative canal pressure, would simply make the disequilibrium even greater resulting in an even stiffer (less compliant) system. It seems reasonable to assume that this is what did occur and that this accounts for the post-exposure compliance curves found.

Using the Valsalva procedure, Loch (1942) found that a moderate increase in middle ear pressure reduced hearing acuity in the lower frequencies by approximately 10 dB. Wever and Lawrence (1954) believed that these effects were probably due to altered tension of the tympanic membrane. They further suggested, however that should the pressure in the middle ear be sufficient, the effect might continue on into the inner ear. One would suspect that in the present investigation the pressure build-up in the middle ear was not sufficient to affect the inner ear since the bone-conduction thresholds were unchanged. Based on the specific effects of both positive and negative pressures on air-conduction thresholds, they concluded that both the damping and stiffness of the tympanic membrane were affected, the damping being responsible for the reduction in sensitivity and the stiffness causing the low tones to be affected primarily.

The possibility exists that the tympanic membrane is affected by the cold air reaching it through the external auditory canal. If the tympanic membrane were to be cooled, the result would be increased stiffness in its action. In order to demonstrate whether or not the tympanic membrane actually is cooled by the cold exposure, each individual's temperature was taken on the tympanic membrane both before and after each exposure session. The temperature of the tympanic membrane was decreased by approximately 0.7 F following the cold exposure. It is unknown to what degree the membrane's action was affected, but, should the tympanic membrane be stiffened as a result of the cooling, the change in impedance would result in depressed low frequency air-conduction thresholds. When the pure-tone air-conduction thresholds had returned to normal so had tympanic temperature. This must certainly be considered as part of the explanation for the threshold shifts observed.

In conclusion, five possible explanations have been presented in order to account for the air-conduction threshold shifts found. The first, that the effects seen were due to generalized body chilling and/or overall muscular contractions, seems unlikely. The second, that the effects were due to changes in the action of the inner ear seems unlikely also. However it is felt that this could be a factor were the exposure longer or the cold more extreme. The most likely explanation for the threshold shifts found appears to be some combination of three physiological effects, namely: 1) subtle changes in the action of the middle ear muscles, 2) increased air pressure in the middle ear and/or 3) a reduction in the vibratory capacity of the tympanic membrane.

The combination of one or more of these factors would result in an increase in the stiffness of the middle-ear system. This change in impedance of the system would be reflected in the post-exposure depressed low frequency pure-tone air-conduction, threshold shifts found. Since the type of audiogram obtained following the cold exposure is similar to that found in patients with adhesive otitis media and pre-clinical otosclerosis, care should be taken to determine how long a patient was out of doors in cold air temperatures immediately preceding an audiometric evaluation. Sufficient time should be allowed for threshold shifts caused by the cold air out doors to fully recover before pure-tone testing is begun to help insure valid pure-tone test results and to aid in avoiding misdiagnoses of middle ear pathology.

Finally this investigation provides further information regarding the effects of altering the normal physiological state of the human middle ear system.

of the subjects. He found the walls of the canal definitely cooled by the exposure and the resultant stiffening of the canal walls to be very noticeable It can be demonstrated by use of the tympanic thermometer that the tympanic membrane is also affected by the cold exposure. It does not seem unreasonable to further assume that the middle ear is somewhat cooler than normal also but undoubtedly not as cool as the external canal. Air of course expands as temperature rises and should the temperature in the middle ear be warmer than that in the external auditory canal, a disequilibrium in air pressure between the external canal and the middle ear cavity would result Under ordinary circumstances, one would expect that this difference in air pressure would be equalized through the action of the eustachian tube For a variety of reasons the eustachian tube may not have been capable of correcting these pressure differentials under the experimental conditions used in this investigation First, a certain minimum amount of pressure difference is necessary to open the eustachian tube probably between 0.5 and 4 mm mercury (Ballenger 1969) The increase in air pressure in the middle ear found in this investigation i.e. approximately +10 mm of water pressure (10 mm water pressure is equal to 0 7 mm mercury) simply may not have been enough to "blow open the eustachian tube. However it may have been enough to cause a slight change in the mechanical action of the middle ear

Secondly it was noted that many of the subjects emerged from the cold room with sniffles. Scott–Brown (1965) and Boies (1957) also comment on temporary congestion, inflammation membrane swelling and nasal discharge as a result of chilling This could certainly have reduced the patency of the eustachian tube as would happen in the case of a common cold. It is more difficult to equalize pressure between the middle ear and outer ear when there is mucosal congestion. In fact the possibility exists that the patency of the eustachian tube may be the key factor that differentiated subjects who shifted from those who did not shift. Those subjects whose eustachian tubes remained most patent were perhaps more able to compensate for the disequilibrium in air pressure and therefore did not show the threshold shift whereas, those subjects who were not able to equalize the pressure between the middle and outer ear showed the threshold shift. This explanation agrees with our findings cited earlier following the cold exposure the middle ear pressure had increased more in the shifters than in the non-shifters. Presumably the non-shifters were able to equalize the air-pressures in their external canals and middle ears, thereby maintaining normal impedance and normal air-conduction thresholds. The differences are small, however as is the number of subjects involved. More important perhaps is the fact that most of the subjects showed some increase in the middle ear pressure following the exposure. This shift in middle ear pressure following the cold exposure was significant at the 0 001 level of confidence.

It was noted previously that post-exposure compliance curves showed reduced compliance under negative canal pressure conditions and enhanced compliance under positive canal pressure conditions. If the middle ear pressure had indeed been somewhat increased and the tympanic membrane displaced outwards slightly this is exactly what one would expect to occur Adding pressure to the external canal would help to bring the air pressure back into equilibrium and allow the tympanic membrane to come closer to its normal (mid-line) position thereby reducing the stiffness (and increasing the compliance) of the system. Withdrawing air from the external canal creating a negative canal pressure, would simply make the disequilibrium even greater resulting in an even stiffer (less compliant) system It seems reasonable to assume that this is what did occur and that this accounts for the post-exposure compliance curves found.

Summary

In Experiment I forty-six subjects were exposed to a cold air temperature of −7 F for 20 min while warmly dressed but with their head and ears exposed Pure tone air and bone-conduction thresholds, various impedance measurements, and tympanic temperature were obtained before and after exposure. In Experiment II nine subjects were exposed to the same cold temperature condition but on three occasions for 20 10 and 5 min The results indicated that bone-conduction thresholds were not affected by cold exposure Air-conduction thresholds however were depressed in about half of the subjects following the cold exposure The longer the exposure the greater was the threshold shift found. These subjects also demonstrated post exposure increased middle ear pressure and decreased tympanic temperature. The threshold shifts were probably due to increased middle ear impedance. Recovery took approximately one hour following the 20 min exposure and 40 min following the 10 min exposure. The 5 min exposure did not affect pure-tone thresholds.

Since the type of audiogram obtained following the cold exposure is similar to that found in patients with certain types of mild conductive hearing impairment, it is important to determine how long a patient was outdoors in cold air temperatures immediately preceeding audiometric testing.

Zusammenfassung

Im ersten Experiment wurden 46 Personen warm gekleidet, aber mit exponiertem Kopf und Ohren für 20 Minuten einer kalten Luft temperatur von −7 Fahrenheit ausgesetzt Vorher und nachher wurden die Schwellen werte für Reinton- (pure-tone) Luft und Knochenleitung sowie verschiedene Impedanzmessungen und die Trommelfelltempera tur bestimmt Im zweiten Experiment wurden 9 Personen derselben kalter Temperatur dreimal ausgesetzt für 20 10 und 5 Minuten Die Ergebnisse zeigten an dass die Knochenleitungsschwellen von einer Kälteexponierung nicht beeinflusst wurden. Die Luftleitungsschwellen jedoch waren bei etwa der Hälfte der Personen nach der Kälteexponierung ge senkt Je länger die Exponierung umso grösser war die aufgefundene Schwellenvershiebung. Diese Personen wiesen nach der Kälte exponierung auch einen erhöhten Mittelohr druck und eine erniedrigte Trommelfelltemperatur auf Die Schwellenverschiebungen waren höchstwahrscheinlich auf eine erhöhte Mittelohrimpedanz zurückzuführen. Die Rückbildung nach 20-minütiger Exponierung dauerte etwa eine Stunde und die nach 10 Minuten etwa 40 Minuten Die 5-minütige Exponierung hatte auf die Reinton- (pure tone) Schwellen keinen Einfluss. Da die Art Audiogramm, die man nach Kälteexponierung erhält derjenigen von Patienten mit gewissen Arten von leichter Leitungshorschwäche ähnelt, ist es wichtig zu bestimmen wie lange unmittelbar vor einer audiometrischen Untersuchung der Patient im Freien in kalter Lufttemperatur war

Introduction

Within the vast sphere of the aetiology of deafness in children the particular field of the pathology of pregnancy likely to affect the normal development of the embryo and later that of the organs already differentiated, causing an impediment to their working in the future, has been studied for only a few decades and is still partly unexplored. As far as prophylaxis is concerned the study of these factors is of primordial importance. Only exact knowledge of teratogenous or noxious agents, whether they are infectious or toxic for example, can lead to progress in research for effective means of prevention.

Unfortunately at present, it is only too often so that an aetiological investigation into the case of a young malformed or deaf child shows the otologic lesion to be of intra-uterine origin.

Embryo

Before approaching the study of the factors likely to perturb the development of the ear before birth it is necessary to review its formation—paying particular attention to the origin of the tissue of each element and to the timing of their evolution, these data help to explain how a particular part of the ear is affected, according to lesion affinities and the moment at which the pathological process intervenes during pregnancy.

The outer ear is of ectodermal origin, the external auditory canal and the pavilion develop from the first branchial fissure and from the outer covering of the first and second arches which border it.

Three ectodermal buds, which later become the pavilion appear at about 43 days. Without going into the details of their development it may be said that the different reliefs of the pavilion are formed by the end of the third month, and reach their final shape between 4 and 5 months.

The tympanum is roughly shaped at about 6 or 7 weeks, the end of the external auditory canal, of ectodermal origin, comes into contact with the endoblast of the tubo-tympanic process from which it is separated by a thin layer of mesoblast. The *pars tensa* the only part formed at this stage is therefore made up of three layers, each of different embryological origin.

The Shrapnell membrane develops at about 6 months when the atticus, in its development, comes into contact with the external auditory canal. It is made up of only two epithelial layers. The tympanum then acquires its final form.

The middle ear—the tympanum and the adjacent cavities are of endodermal origin, while the ossicles are formed out of the mesoblast. The atrium and the atticus become distinct at about 10 weeks. For a long time they are full of reddish mesenchymatous tissue and do not reach their final form until the sixth

Introduction

Within the vast sphere of the aetiology of deafness in children the particular field of the pathology of pregnancy likely to affect the normal development of the embryo and later that of the organs already differentiated, causing an impediment to their working in the future, has been studied for only a few decades and is still partly unexplored. As far as prophylaxis is concerned, the study of these factors is of primordial importance. Only exact knowledge of teratogenous or noxious agents, whether they are infectious or toxic for example, can lead to progress in research for effective means of prevention.

Unfortunately at present it is only too often so that an aetiological investigation into the case of a young malformed or deaf child shows the otologic lesion to be of intra-uterine origin.

Embryo

Before approaching the study of the factors likely to perturb the development of the ear before birth it is necessary to review its formation—paying particular attention to the origin of the tissue of each element and to the "timing" of their evolution: these data help to explain how a particular part of the ear is affected, according to lesion affinities and the moment at which the pathological process intervenes during pregnancy.

The outer ear is of *ectodermal origin*: the external auditory canal and the pavilion develop from the first branchial fissure and from the outer covering of the first and second arches which border it.

Three ectodermal buds, which later become the pavilion, appear at about 43 days. Without going into the details of their development it may be said that the different *reliefs of the pavilion* are formed by the end of the third month, and reach their final shape between 4 and 5 months.

The tympanum is roughly shaped at about 6 or 7 weeks: the end of the external auditory canal, of ectodermal origin, comes into contact with the endoblast of the tubo-tympanic process from which it is separated by a thin layer of mesoblast. The *pars tensa*, the only part formed at this stage, is therefore made up of three layers, each of different embryological origin.

The Shrapnell membrane develops at about *6 months when the atticus, in its development,* comes into contact with the external auditory canal. It is made up of only *two epithelial layers. The tympanum then acquires its final form.*

The middle ear: the tympanum and the adjacent *cavities are of endodermal origin*, while the ossicles are *formed* out of the mesoblast. *The atrium and the atticus* become distinct at about *10 weeks*. For a long time they are full of reddish mesenchymatous tissue and do not reach their final form until the sixth

month. The Fallopian canal is completed at about the same time.

The ossicles appear very early 33 days for the early form of the stapes 45 days for the incus the beginning of the 2nd month for the malleus. By 6 months ossification is almost complete

The inner ear begins to take shape in the second week after conception the auditory placode develops from the ectoblast as a simple cupula at first which deepens to become the aural vesicle

This divides itself into sections making several diverticula the endolymphatic canal begins to form at about 30 days the utriculus producing the early forms of the semi circular canals, first the superior semicircular canal (36 days) posterior and finally exterior (46 days) sacculus.

The cochlear tube becomes distinct at about 36 days. By the end of the 7th week the base spiral is completed. At 70 the two-and a-half turns are completed.

The vestibular apparatus develops at about 9 weeks in its final form.

However histological modifications continue especially as far as the organ of Corti is concerned. This develops rapidly from the fourth month onwards and is complete at about 6 months.

Ossification of the aural capsule, made out of the mesenchyma surrounding the membranous labyrinth is completed by the 23rd week.

The connections of the nerves are established between 7 and 8 weeks.

It must be borne in mind that the growth of the brain will continue up to 12 years, reaching its acme between 0 and 2 years.

Between the 6th month and birth only a few minor modifications will occur at this stage the annexes are being finished involving the tympanum a virtual cavity at this period which will not become empty until birth the Fallopian canal, the ossification of which continues, and the stapes, the volume of which is reduced as it loses its original medullar tissue.

But although anatomical and histological development is practically finished it must be stressed that histochemical modifications are still possible particularly in the case of the sensory cells of the organ of Corti, the cytochemical structure of which is finished at the end of the first month after birth.

Definitions

This information about the embryo shows how difficult it is to put a definite date on the moment during pregnancy at which pathological incidents likely to affect the developing ear occur

In the strict sense of the term an embryopathy is something affecting the embryo that is, the product of conception up to 3 months the period during which most of the organs become distinct.

From 4 months onwards the product of conception has become a foetus and one should talk of foetopathy This is no longer a period of differentiation but of growth.

In fact the borderline is badly placed although the ear is more or less anatomically constituted by the end of the 3rd month histological modifications continue until the 6th month and the histochemical evolution probably goes on beyond that.

In addition the effect on the ear of different pathological processes is not necessarily the same even at the same moment of gestation an embryopathy i.e a disorder during the first 3 months, is not necessarily synonymous with malformation (at least not as far as is anatomically detected). In the opposite way a given agent could produce the

same result whether it had its effect in the third or fifth month, for example.

It therefore seems more logical to consider the factors likely to perturb the normal functioning of the ear globally according to types, irrespective of the time of intervention during pregnancy in other words, *without making any distinction between embryopathy and foetopathy*

However the ways in which they act must *still be known.*

Physio-pathological Data

The teratogenous or noxious agent may intervene in one of two ways: (i) it may have an *indirect action* the pathogenic factor not reaching the foetus.

either by the intermediary of a disturbance of the metabolism (deficiency or excess). It is well known that there are many metabolic modifications during infectious diseases. Experiments with animals have shown the teratogenous role of a deficiency of vitamin A or B in the mother for example

or by means of placentary anoxemia,

or by means of a toxin, in particular those produced by viruses.

(ii) The pathogenic agent may on the other hand, have a *direct action* passing through the placenta. This involves the question of the permeability of the placenta as far as the given factor is concerned.

It is well known that bacteria and parasites may pass through the placenta (rarely during the first few weeks) such as streptococci, meningococci, spirochaeta, malaria protozoa, toxoplasma.

Viruses may also pass through the placenta, for example measles, rubella, influenza, herpes.

As for *toxic substances, their passage is* easier because of their lower molecular weight, therefore gases (anaesthetics) and volatile substances pass through in a few minutes.

Hydrolytic substances, ethyl alcohol in particular *pass through the placenta if their* molecular weight is not too high (above 1 000 the placenta is impermeable).

Certain metals and metalloids and their salts (arsenic, bismuth, iodine, mercury lead) organic compositions (atropine, morphine, nicotine for example) may also pass through.

The consequence is that many medicamentous substances may pass through the placenta the list would be a long one but streptomycin, kanamycin and quinine must be remembered since they are important in the present study

The Clinical Study

This leads to the successive consideration of the different causes likely to bring about embryopathy or foetopathy affecting the ear

I. INFECTIOUS CAUSES

In this group, viral causes head the list, and, of course rubella.

** 711841

(a) Viral causes

Since 1941 British, American and Australian publications have drawn attention to the role of rubella in pregnant women as a determining factor of embryopathy when it occurs during the first three months.

Gregg gave the first description of rubella embryopathy in its ophthalmological aspects.

month. The Falloplan canal is completed at about the same time

The ossicles appear very early 33 days for the early form of the stapes, 45 days for the incus, the beginning of the 2nd month for the malleus. By 6 months ossification is almost complete.

The inner ear begins to take shape in the second week after conception the auditory placode develops from the ectoblast, as a simple cupula at first which deepens to become the aural vesicle

The Clinical Study

This leads to the successive *consideration of the different causes likely to bring about embryopathy or foetopathy affecting the ear.*

I. INFECTIOUS CAUSES

In this group, viral causes head the list, and, of course, rubella.

(a) Viral causes

Since 1941 British, American and Australian publications have drawn attention *to the role of rubella in pregnant women as a determining factor of embryopathy when it occurs during the first three months.*

Gregg gave the first description of rubella embryopathy in its ophthalmological aspects.

He observed cataracts in thirteen new-born babies the mothers of which had had rubella in the first months of pregnancy during an epidemic in Australia in 1940

The following year as a result of a systematic survey Swan indicated the possibility of deafness accompanying the ocular disorder in cases of rubella embryopathy Gregg s triad involving cataract, deafness and congenital cardiopathy was specified in 1944

Since then much work has been done in Britain (Martin, Hopkins) America (Prendergast, Beswick Warner) Switzerland (Franceschetti Bamatter and Bourquin) The first French observation was made in 1946 (Debré Saint and Thieffry)

Many statistics have been published since then in an attempt to determine the proportion of cases of deafness among the effects of rubella during pregnancy on the one hand and the proportion of cases of deafness for which rubella was responsible on the other

The figures vary considerably according to Swan rubella is responsible for deafness in 59 9% of cases according to Meyer 72.5% and according to Kuntzel 63 6% (the latter having gathered together all 1 048 cases in the world published between 1941 and 1952) when the mother suffers from rubella during the first months of pregnancy

Inquiries into the different causes of deafness in children also vary in attribution of responsibility to rubella embryopathy (9% according to Erickson 9% again according to Schwann 6 9% according to Van Gilse 1 3% according to Candiotti, 37 1% according to Hay) Studies recently undertaken at the Institut d Audiophonologie in Lyon have shown rubella to be responsible seven times out of 100 partially deaf children fifteen times in another study concerning 190 profoundly deaf children giving a total percentage of 8 4

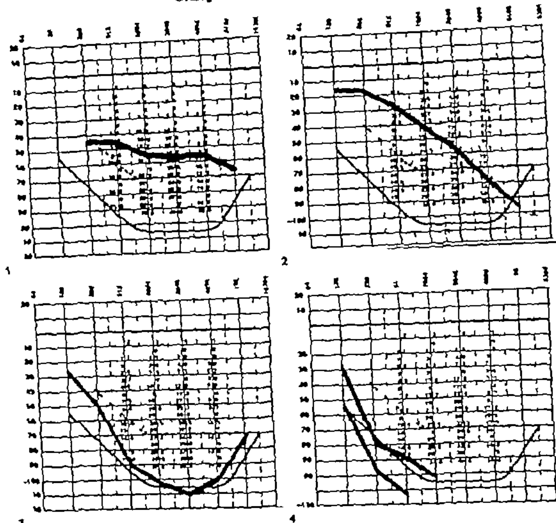
In general the gravity of lesions caused by rubella embryopathy depends on the time of infection rather than the gravity of the infection itself

It is widely accepted that from 3 to 7 weeks it causes ophthalmological lesions, cataract and microphthalmia being the most typical and the most frequent from 5 to 8 weeks cardiovascular lesions (most frequently persistence of the arterial canal, interauricular and interventricular communication) from 6 to 9 weeks stomatological lesions

Lastly microcephalia and mental retardation are frequently associated and lower the educational possibilities when accompanying deafness even more than ocular lesions.

Some authors have even tried to establish a still more precise embryopathic timetable" in this way Brent and Tondury specify that a cataract results when the pregnant woman suffers from rubella between 29 and 35 days, that a cardiopathy regularly results between 36 and 49 days, a lesion of the inner ear between 50 and 63 days.

In fact such a timetable is not always respected, as is shown by simultaneous lesions of several organs associated ocular and auditory lesions, for example.



The possibility of auditory embryopathy throughout the first three months of pregnancy must therefore be admitted this is in fact the opinion of the majority

The problem of "unapparent cases of rubella in the mother must certainly be discussed but one must be very cautious about confirming such cases and insist on positive results to a serological examination of the child.

Anatomo-pathological lesions always affect the inner ear Little is known about them yet since histological observations of rubella ears are comparatively rare

Real malformations seem to be fairly rare rudimentary Corti sensory cells, underdeveloped vascular stria and tectorial membrane (Kuntzel Lindsay)

Most of the time the trouble is due to small dispersed extravasations of blood (Kelemen) haemorrhages which although very small can cause extensive damage to the inner ear in the basilar membrane or the vascular stria

Figs 1-4 Rubella embryopathy: Five types of curves (C.A.).

The posterior labyrinth is not usually affected.

In fact anatomo-pathological observations are still very sparse, and thus explains to a certain extent the multiplicity of pathogenic theories expressed: direct action of the virus, a real intracellular parasite, electively attaching itself to dividing tissues (Claverie) vascular mechanism (Schwann & Hurst, Kelemen), metabolic disturbances caused by enzyme inhibition due to the virus (Mann & Warkany).

Clinically

Rubella embryopathy is responsible for lesions of the inner ear: apart from Leicher all authors of papers are quite definite about the constant integrity of the middle and outer ear.

Perceptive deafness is generally severe, but only rarely total.

The curve of the graph may be very varied: horizontal depressed, sloping down from low to high frequencies.

Although both ears are affected, one side is generally worse than the other. Some authors have even described unilateral deafness (Jackson & Fisch) although this seems to be exceptional.

As a general rule the effect on hearing is great, severe partial deafness or profound deafness, so that even isolated the diagnosis

He observed cataracts in thirteen new born babies, the mothers of which had had rubella in the first months of pregnancy during an epidemic in Australia in 1940

The following year as a result of a systematic survey Swan indicated the possibility of deafness accompanying the ocular disorder in cases of rubella embryopathy Gregg's triad involving cataract, deafness and congenital cardiopathy was specified in 1944

Since then much work has been done in Britain (Martin Hopkins) America (Prendergast Beswick Warner) Switzerland (Franceschetti Bamatter and Bourquin) The first French observation was made in 1946 (Debré Saint and Thieffry)

Many statistics have been published since then in an attempt to determine the proportion of cases of deafness among the effects of rubella during pregnancy on the one hand and the proportion of cases of deafness for which rubella was responsible on the other

The figures vary considerably according to Swan rubella is responsible for deafness in 59 9% of cases according to Meyer 72.5% and according to Kuntzel 63 6% (the latter having gathered together all 1 048 cases in the world published between 1941 and 1952) when the mother suffers from rubella during the first months of pregnancy

Inquiries into the different causes of deafness in children also vary in attribution of responsibility to rubella embryopathy (9% according to Erickson 9% again according to Schwann 6 9% according to Van Gilse 1 3% according to Candiotti 37 1% according to Hay) Studies recently undertaken at the Institut d Audiophonologie in Lyon have shown rubella to be responsible seven times out of 100 partially deaf children fifteen times in another study concerning 190 profoundly deaf children giving a total percentage of 8 4

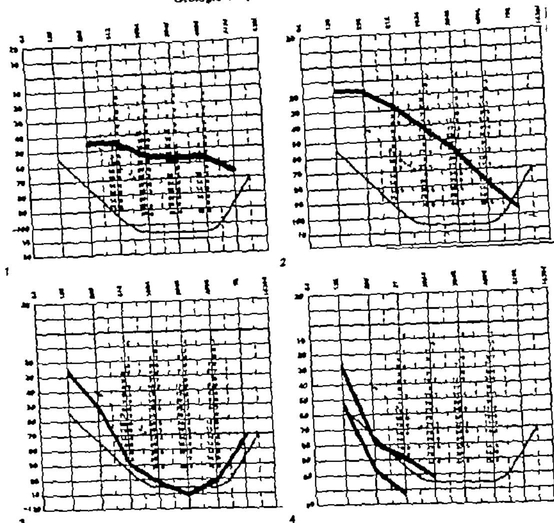
In general the gravity of lesions caused by rubella embryopathy depends on the time of infection rather than the gravity of the infection itself

It is widely accepted that from 3 to 7 weeks it causes ophthalmological lesions, cataract and microphthalmia being the most typical and the most frequent from 5 to 8 weeks cardiovascular lesions (most frequently persistence of the arterial canal, interauricular and interventricular communication) from 6 to 9 weeks stomatological lesions.

Lastly microcephalia and mental retardation are frequently associated and lower the educational possibilities when accompanying deafness even more than ocular lesions.

Some authors have even tried to establish a still more precise "embryopathic timetable in this way Brent and Tondury specify that a cataract results when the pregnant woman suffers from rubella between 29 and 35 days, that a cardiopathy regularly results between 36 and 49 days a lesion of the inner ear between 50 and 63 days.

In fact such a timetable is not always respected, as is shown by simultaneous lesions of several organs associated ocular and auditory lesions, for example.



The possibility of auditory embryopathy throughout the first three months of pregnancy must therefore be admitted this is in fact the opinion of the majority

The problem of unapparent cases" of rubella in the mother must certainly be discussed but one must be very cautious about confirming such cases and insist on positive results to a serological examination of the child.

Anatomo-pathological lesions always affect the inner ear Little is known about them yet since histological observations of rubella ears are comparatively rare

Real malformations seem to be fairly rare rudimentary Corti sensory cells, underdeveloped vascular stria and tectorial membrane (Kuntzel Lindsay)

Most of the time the trouble is due to small dispersed extravasations of blood (Kelemen) haemorrhages which although very small can cause extensive damage to the inner ear in the basilar membrane or the vascular stria.

Figs. 1-4. Rubella embryopathy: Fo types of curves (C.A.).

The posterior labyrinth is not usually affected.

In fact anatomo-pathological observations are still very sparse, and this explains to a certain extent the multiplicity of pathogenic theories expressed: direct action of the virus, a real intracellular parasite, electively attaching itself to dividing tissues (Claverie), vascular mechanism (Schwann & Hurst, Kelemen), metabolic disturbances caused by enzyme inhibition due to the virus (Mann & Warkany).

Clinically

Rubella embryopathy is responsible for lesions of the inner ear: apart from Leicher all authors of papers are quite definite about the constant integrity of the middle and outer ear.

Perceptive deafness is *generally* severe, but only rarely total.

The curve of the graph may be very varied: horizontal, depressed, sloping down from low to high frequencies.

Although both ears are affected, *one* side is generally worse than the other. Some *authors* have even described unilateral deafness (Jackson & Fisch) although this seems to be exceptional.

As a general rule the effect on hearing is great, severe partial deafness or profound deafness, so that even isolated the diagnosis

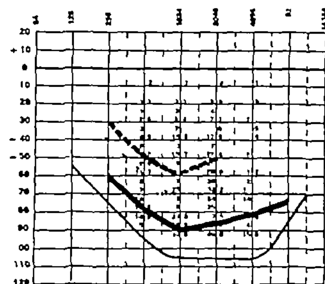


Fig 5 Congenital syphilis.
--- C O curve
—— C A curve

may be reached at an early stage by an attentive family even before lateness in beginning to speak awakens suspicion Of course the presence of other elements of the rubella traid congenital cataract or cardiac malformation *now means a systematic auditory examination* which facilitates early diagnosis of deafness.

The proof that rubella is the cause can now be provided by the search for the virus itself and above all by serological examinations of new born babies and young children Recent studies have revealed the presence of viruses in the placenta systematic research at the time of delivery would provide a conclusive argument.

Similarly deafness has been found after measles (Schachter Candiotti) influenza (Ellet Hopkins Massol) mumps (Hay Cronvald, Selander) and even poliomyelitis (Kelemen) shingles or chicken pox.

In fact, at the moment the lack of cases described makes it possible to retain these factors only as probable causes without certain confirmation because the possibility can not be eliminated.

Given the permeability of the placenta as regards most viruses and the results obtained by the innoculation of animals with viruses, logically large scale statistical inquiries should prove the influence of many viruses in the causation of auditory embryopathies.

Another argument carrying weight would be provided by evidence of the presence of the virus itself in the deaf baby or by the positive nature of specific serological reactions. Much is hoped for in this field from the research at present being undertaken by the Institut d Audiophonologie of Lyon in collaboration with the Laboratoire de Recherches Virologiques du Centre d Hygiène de l Enfance

(b) Microbic causes

Once again there are two categories of embryopathy or foetopathy those resulting from treponema now well known and those attributable to other germs.

In fact, apart from syphilis, observation are very sporadic and varied Candiotti mentions cases of deafness after diphtheria typhoid pneumonia during pregnancy Albouy mentions scarlatina in the fifth month of gestation *as a cause of deafness, also associated* with macular dysplasia.

Bernabei, Bordley Fowler also mention various microbic infections in the statistical studies they have made

Once again it is difficult to confirm the role of microbic agents as a cause of deafness. It would appear that miscarriage was more frequent than lesions of the foetus in cases of serious infections of pregnant women

On the other hand *congenital syphilis* is well known as a cause of foetopathy *its in*cidence is now limited, whereas it used to be extensive

Syphilitic infection does not cause malformation since the treponema cannot pass through the barrier of the placenta before the fifth month

There are two distinct forms (*a*) *meningoneuritis* of the acoustic apparatus, which is rare it occurs either in babies or at a later stage and is often associated with other nervous disorders, *(b) it may on the other hand,* show itself in the form of retarded labyrin

thitis, which is more frequent it affects children, especially girls, between 10 and 15 years old. it is the last stage of the Hutchinson triad (being preceded by deterioration of the teeth and interstitial keratitis).

The condition develops unevenly in spurts, affecting the ears unequally The curve of the graph is of mixed deafness at first, then osseous conduction and aerial conduction become the same.

The posterior labyrinth always suffers from hypoexcitability or inexcitability to vestibular tests. The Siegle test reveals nystagmus towards the opposite side: Hennebert's syndrome

Diagnosis is based on clinical observations, deafness is accompanied by dental and ocular deterioration (keratitis, hydarthrosis of the knees snub-nose, perforation of the velum, malformations of the long bones. Serological tests (Bordet–Wassermann and in particular Nelson) confirm it.

II PARASITE CAUSES

Although malaria haemonites are known to be able to pass through the placenta, a disorder of the ear never seems to have been described as having resulted from this condition during pregnancy

On the other hand another parasite, toxoplasma—a small protozoon—was declared responsible for embryopathy as early as 1938 by Wolf Cowen & Paige. Lesion of the brain (hydrocephaly comitiality) and eyes (characteristic dysplasia of the macula) were described in the first place. It was not until 1950 that Campbell & Clifton reported cases of deafness in children having congenital toxoplasmosis with ocular disorders. Since then other observations of auricular toxoplasmosis have been published (Dietzel, Feinmesser & Landau, Grimaud & Wayoff) and now the possibility of such a cause must not be underestimated, especially as it is a widespread condition (only 13% of the population over 30 would still have a negative serological reaction according to Lelong).

The anatomo-pathological lesions have been described by Kelemen who observed the presence of calcification, not only of the *brain* but also of the vascular stria and the spiral ligament, associated *with an inflammation* of the whole of the vestibule as well as in the middle ear

From a pathogenis point of view congenital toxoplasmosis is the result of an infection of the foetus during an illness of the mother Several points should be stressed. the parasitosis of the mother is generally not apparent, the contamination of the foetus is not constant throughout the mother's illness whenever it may occur there seems to be no risk of transmission during the first six weeks of pregnancy

Because of the size of the parasite, a lesion of the placenta is necessary for it to pass through into the foetal circulation. This lesion would occur during the parasitemic phase of the mother's toxoplasmosis.

The phase of toxoplasmic infection of the child at birth depends on the moment of infection during pregnancy (i) primary or parasitemic, characterized by icterus with hepatosplenomegaly polyadenopathies and serious visceral disorders which are *often fatal* (ii) secondary causing evolutive encephalomyelitis (somnolence, hypotonia or hypertonia, convulsions) with *modifications* of the cephalo-rachidial fluid, (iii) finally tertiary that is the phase of consequences essentially characterized by cerebral disorders (microcephalus or hydrocephaly convulsions), *ocular disorders (chorioretinitis* with the characteristic *appearance of the fundus*) and possibly auditory disorders.

Perceptive deafness, indicating lesions caused by the parasite to the neuro-sensorial elements of the labyrinth. It seems to vary in *degree: observations* published so far report either slight troubles (Dietzel) or severe deafness (Grimaud & Wayoff).

Diagnosis is at first based on clinical ex-

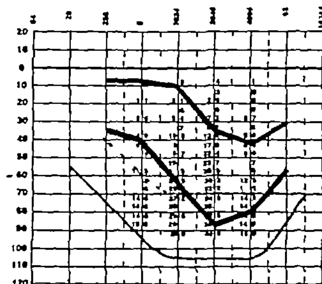

Fig 6 Congenital toxoplasmosis. Two types of curves (C.A.).

amination deafness associated with chorioretinitis, with the characteristic deterioration of the fundus, and with hydrocephaly or microcephalia with calcifications visible by means of radiography is most likely to lead to a diagnosis of congenital toxoplasmosis.

It is confirmed by serological tests showing specific antibodies. (i) either directly by action on a living strain of toxoplasma Savin's lysis test. Up to 2 years a proportion of over 1/16th is significant. After that the proportion must be over 1/128th. (ii) or indirectly by complement fixation reaction. The reaction is positive when over 1/64th.

It must, however be pointed out that because of the frequency of the illness the significance of serological tests varies according to the child's age during the first three months the presence of antibodies may be due to an infection of the mother before pregnancy. The transmitted antibodies disappear at about 3 months. It is imperative to follow the development of the proportion of antibodies as time progresses. From 3 months to 1 year positive reactions give confirmation of a diagnosis of congenital toxoplasmosis that is the only time at which serological examination can be categorical. Over 1 year positive reactions may correspond to either congenital or acquired toxoplasmosis.

The systematic use of these serological tests will probably make it possible in future to attribute to toxoplasmosis *certain* cases of congenital deafness the explanation of which otherwise remained vague. As the illness is widespread it may be responsible for more cases of deafness than have yet been estimated.

III. IONISING RADIATIONS

The dangers to the embryo and the foetus of radiation are known in general. It can cause mutation induced by its effects on the gonads, leukaemia and neoplastic processes, and morphological and functional anomalies.

Experiments with animals (Kelemen) aiming at demonstrating the behaviour of the auditory organ when the pregnant female undergoes irradiation have shown serious endo*cranial malformations with intracochlear* and pericochlear haemorrhages but without anomalies in the development of the labyrinth.

As far as human beings are concerned there is little literature specifically concerning the ear in spite of widespread inquiries undertaken in Japan for example, after the massive irradiations due to the atomic bombardments.

However on the basis of experimental data it seems advisable on the one hand to limit irradiation in the case of pregnant women and, on the other hand to bear this possibility in mind when attempting to define the cause of the aural disorders of a deaf or malformed child.

IV TOXIC CAUSES

(a) Exogenous

The dangers of medicaments and toxins to the ovum for a long time asserted by experimenters and suspected by clinicians, recognised in particular cases, has reached the forefront of interest over the past ten years since the dramatic consequences of the use of Thalidomide by pregnant women.

Many substances may pass through the placenta and damage the auditory organ. As early as 1935 Taylor said that "quinine, salicylates, alcohol pass through the placenta and are present in the foetus in the same concentration as in the mother's circulation"

In reality it is more usual to find the foetus dead *in utero* as a result of absorption of toxic substances, and until recent years few conclusive observations of deafness caused by toxic embryopathy or foetopathy had been reported. Of these it is necessary to mention auditory disorders linked with massive and prolonged doses of *streptomycin* during pregnancy as reported by Boletti & Croatto, Rebattu & Lesne.

In the study produced by the Institut d'Audiophonologie of Lyon about partial deafness already quoted, an attempted abortion at about the 10th week of pregnancy by use of quinine was the only cause of perceptive deafness of medium gravity

These medicaments seem to damage the sensory cells of the organ of Corti, but have no teratogenic effect properly speaking.

The same is not true of Thalidomide: since 1960 numerous publications have stressed the role of this substance as the cause of multiple malformations when administered during the first months of pregnancy

It is remarkable, as far as the ear is concerned, that the malformations involved not only the outer and middle ear (Partsch, Maurer Lenz, Hepp Petersen) but also the inner ear (Kleinsasser Schlothane) the two disorders being observed simultaneously in the same child. Terrahe produced a detailed radiotomographic study of these lesions in a group of 37 children from 3 to 4 years old, suffering from bilateral malformations of the outer ear-middle ear whose mothers had taken Thalidomide during the first two months of pregnancy He observed simultaneous malformations of the inner ear in 33 of them, the malformations were very varied, dysplasia of the external and superior semicircular canals; absence of all canals; rudimentary double labyrinth, absence of fenestrae, accompanying, of course, severe perceptive deafness.

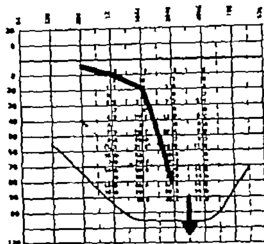

Fig. 7 Toxic foetopathy Streptomycin (C.A. curve).

Many other substances have been recognised as being responsible for a multitude of embryopathies and foetopathies, for example. cytostatics, sexual hormones, dicoumarol, derivatives of digitalis, although little is known about their effect on the ear

Synthetic antithyroid drugs should be pointed out: it is known that if they are administered to the mother during gestation they may give rise to goitre with hypothyroidism in the new-born baby

The classic forms of deafness from congenital myxoedema are known. the auditory disorder takes its place among disturbances of growth and psychomotor retardation. It does not therefore seem illogical to admit that antithyroid drugs taken by the mother cause deafness in the child. our statistics for partial deafness contain an observation where this hypothesis may be considered very probable.

Before ending this chapter on exogenous toxins, the possible role of medicaments likely to damage the inner ear by means of anoxia used during *labour and delivery* must not be neglected. *These* are volatile anaesthetics, barbiturates, neuroleptics which all pass into the foetal circulation and may have marked depressive effects on the child's respiratory

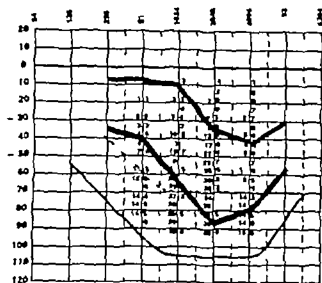

Fig 6 Congenital toxoplasmosis. Two types of curves (C.A.)

amination deafness associated with chorioretinitis, with the characteristic deterioration of the fundus, and with hydrocephaly or microcephalia with calcifications visible by means of radiography is most likely to lead to a diagnosis of congenital toxoplasmosis.

It is confirmed by serological tests showing specific antibodies. (i) either directly by action on a living strain of toxoplasma. Savin's lysis test. The Place of Embryopathy and Foetopathy as Causes of Deafness in Children

It is of interest to refer to global statistics in order to assess the importance of embryopathy and foetopathy as causes of deafness in children.

The study of rubella embryopathy has already enabled us to consider this problem and it would be useful to take it up as a whole.

It must be said, however that most statistics do not analyse simultaneously malformations of the outer or middle ear and perceptive deafness caused by disorders of the inner ear so that it is difficult to compare the frequencies of both types.

We are more concerned with disorders of the inner ear and give two recent statistical reports from the Institut d'Audiophonologie of Lyon—one concerning partial deafness and the other profound deafness.

Embryopathy and foetopathy are responsible for 12% of cases in Table I (8% certain, 4% probable) 9.5% of cases in Table II (5.3% certain, 4.2% probable), that is 10.6% overall.

However these studies show how often the cause of deafness remains unknown (30–40%), emphasising how much more research needs to be done, particularly in the field of the pathology of pregnancy where, as we have already said, much uncertainty remains.

Table I. *Aetiology of partial deafness in young children (100 cases)*

Genic causes (22%)		
Hereditary or family deafness	22	15 certain 7 probable
Antenatal causes, embryopathy and foetopathy (12%)		
Rubella	7	6 certain 1 probable
Syphilis	1	
Toxic	2	1 certain (quinine) 1 probable (anti-thyroid treatment)
Dysgravidia (haemorrhage during pregnancy)	2	probable
Neonatal causes (23%)		
Birth trauma	1	probable
Anoxia	9	8 certain 1 probable
Nuclear icterus	6	
Prematurity	7	2 with anoxia 5 without anoxia
Post-natal causes (13%)		
Meningitis: cerebro-spinal	3	
tubercular	2	
viral	1	
Encephalitis	4	certain 2 probable
Mumps	1	
Labyrinthic middle otitis		probable
Causes unknown (30%)		

centres, causing anoxia unless sufficient oxygenation is maintained.

It is well known that the sensory cells of the organ of Corti are particularly fragile as regards anoxia which causes widespread haemorrhages often affecting the whole of the central nervous system.

Here foetal pathology becomes bound up with neonatal pathology and in practice it is often difficult to determine the exact moment at which the child's condition began particularly as the result is the same neurological lesions of varying extent are associated with variable degrees of perceptive deafness.

(b) Endogenous

This field, which involves embryopathies with *humoral metabolic and endocrine causes* is as yet little known in any case it is often difficult to distinguish when the mother is suffering from a long-term condition existing since before the pregnancy between what is caused by the disease itself and what is caused by the treatment it necessitates. This is the case with diabetes for example a long time ago insulin hypoglycemia was found to be responsible for teratogenous effects Petersen & Tygstrup have shown that the existence of vascular lesions in the mother conditions the frequency of foetal malformations.

As far as the effect of diabetes on the development of the ear is concerned Kelemen provides interesting histological arguments anatomo-pathological examination of foetuses of 4 and 6 months (therapeutic abortion dictated by the gravity of the mother's diabetes) showed normal development of the different parts of the ear and particularly of the cochlea, but the existence of diffuse haemorrhages in the cochlear canal and the vestibulum

It would therefore seem that the characteristic feature in this case is the fragility of the blood vessels.

Kelemen made the same observation about foetuses of mothers suffering from grave nephritis.

This vascular fragility once acquired, is incurable and may in ulterior pathological circumstances give rise to new lesions (for example during delivery)

In fact the study of the different statistics published leads to a belief that any disease of the mother during pregnancy may cause auditory embryopathy or foetopathy whether it be metabolic or humoral vascular or endocrine.

With this in mind dysgravidia with threatened miscarriage, repeated haemorrhages during the greater part of the pregnancy must be admitted

The facts already known about auricular embryopathies and foetopathies are incomplete and fragmentary Alongside well-established perfectly studied facts there are many unknowns.

In fact most inquiries made into this subject up to now have been retrospective working backwards from the aural lesion they have made proof or suspicion of a causal lesion possible but not an appreciation of the exact risk

Only systematic prospective studies starting from the pathological element during pregnancy will in future allow for an evaluation of the nature and above all the extent of these risks for the baby yet to be born In other words, there must be strict surveillance of pregnancies that may be considered high risk and systematic auditory examination of all these children immediately after birth in order to draw valid conclusions.

The Place of Embryopathy and Foetopathy as Causes of Deafness in Children

It is of interest to refer to global statistics in order to assess the importance of embryopathy and foetopathy as causes of deafness in children.

The study of rubella embryopathy has already enabled us to consider this problem and it would be useful to take it up as a whole.

(b) Endogenous

This field, which involves embryopathies with *humoral metabolic and endocrine causes* is as yet little known in any case it is often difficult to distinguish when the mother is suffering from a long-term condition existing since before the pregnancy between what is caused by the disease itself and what is caused by the treatment it necessitates. This is the case with diabetes for example a long time ago insulin hypoglycemia was found to be responsible for teratogenous effects Petersen & Tygstrup have shown that the existence of vascular lesions in the mother conditions the frequency of foetal malformations.

As far as the effect of diabetes on the development of the ear is concerned Kelemen provides interesting histological arguments. anatomo-pathological examination of foetuses of 4 and 6 months (therapeutic abortion dictated by the gravity of the mother s diabetes) showed normal development of the different parts of the ear and particularly of the cochlea, but the existence of diffuse haemorrhages in the cochlear canal and the vestibulum.

It would therefore seem that the characteristic feature in this case is the fragility of the blood vessels.

Kelemen made the same observation about foetuses of mothers suffering from grave nephritis.

This vascular fragility once acquired is incurable and may in ulterior pathological circumstances give rise to new lesions (for example during delivery)

In fact the study of the different statistics published leads to a belief that any disease of the mother during pregnancy may cause auditory embryopathy or foetopathy whether it be metabolic or humoral vascular or endocrine.

With this in mind dysgravidia with threatened miscarriage, repeated haemorrhages during the greater part of the pregnancy must be admitted.

The facts already known about auricular embryopathies and foetopathies are incomplete and fragmentary Alongside well-established, perfectly studied facts there are many unknowns.

In fact most inquiries made into this subject up to now have been retrospective working backwards from the aural lesion they have made proof or suspicion of a causal lesion possible but not an appreciation of the exact risk

Only systematic prospective studies starting from the pathological element during pregnancy will in future allow for an evaluation of the nature and above all the extent of these risks for the baby yet to be born In other words there must be strict surveillance of pregnancies that may be considered "high risk and systematic auditory examination of all these children immediately after birth in order to draw valid conclusions.

Finally it could be dangerous to extrapolate experimental results: for example a considerable number of medicaments may be teratogenous in animals in certain conditions of experimental procedure (salicylates or corticoids in particular). Their use in human therapy has shown that they are not necessarily noxious in normal conditions. Should a pregnant woman be deprived of aspirin because salicylate derivatives may be teratogenous in mice, rats or hamsters?

Experiments with animals produce hypotheses or suspicions rather than absolute certainties. Properly conducted, however they can be of great help in the selection of new medicaments. They make it possible if not to avoid with certainty at least to reduce to the minimum the therapeutic risk. It is due to the rigorousness of French legislation in this domain that France was spared the damage wrought by Thalidomide.

In practical terms, what prophylactic measures can be considered at the moment as far as embryopathy and foetopathy are concerned?

If one considers toxic causes and particularly medicamentous ones, within the limits of our present knowledge it is wisest to limit as far as possible the administration to pregnant women of medicaments whose innocuousness to the foetus has been proved by long experience.

If one considers infectious and, particularly viral causes, vaccination becomes all-important. Rubella in pregnant women represents a serious risk to the embryo which is now well known. A vaccine has recently been developed, its systematic use is still being discussed.

Although it does not seem very logical to make it compulsory for all girls of school age, since immunity as in the case of many vaccinations, disappears in time, it would desirable to devise a procedure of the following type. serological test at the time of the prenuptial examination in order to find out how many antibodies the young woman has; compulsory vaccination when immunity is found to be inadequate. In this case pregnancy must be strictly forbidden during three months since there would then be a major teratogenous risk.

Finally if the development of the pregnancy is in any way perturbed (intercurrent illness, threatened miscarriage, long-term therapy) very strict surveillance is essential at the time of delivery in order to avoid any factor likely to aggravate the situation—anoxia in particular—by affecting structures which are already fragile as Kelemen stresses.

Treatment

Although it is not logical to distinguish between malformations and lesions of the ear while studying the causes of embryopathies and foetopathies, the therapeutic problems vary nevertheless, according to the following circumstances. (i) whether the child has an apparent malformation of the outer or middle ear (ii) whether the child is deaf without apparent malformation.

There follows an indication of the principles which should guide therapy in each case, respectively

I. MALFORMATIONS OF THE EAR

These malformations may be very varied. They affect above all the outer and middle ear but also, more often than was previously thought, the inner ear

The pavilion, the external auditory canal, the ear drum, the tympanum, the chain of ossicles, the labyrinth, may all be affected in different degrees, including all the intermediate stages between minor and major aplasia and may be described in many dif

Table II *Aetiology of profound deafness in young children (190 cases)*

Genic causes (19.7%)

Post-natal causes (20.9%)		
Meningitis: cerebro-spinal	[illegible]3	
tubercular	[illegible]	
viral	2	
Encephalitis	1	
Labyrinthic middle otitis	1	
Whooping cough	1	
Typhus	1	
Myoedema	1	
Toxic	3	
Various causes	5	
Causes unknown (40.[illegible])		

Prophylaxis

Because of the situation stated above, it is difficult at present to determine *preventive measures* and the most important thing to do is to decide upon the directions of future research.

Only the multiplication of clinical observations can bring to light the teratogenous or noxious effects on the ear of a *specified agent.* A national or international "central register" gathering together all this information would be desirable. *prospective* inquiries beginning with the pathological element occurring during pregnancy would contribute more to the appreciation of the risk incurred by the unborn child than retrospective surveys.

Alongside this clinical research experiments on *animals* could provide information of use in the field of both viral and toxic embryopathy and *foetopathy.* The limits must however be delineated.

The permeability of the placenta varies considerably between one species and another and between an animal species and human beings. It may also vary in certain circumstances (metabolic modifications, for example).

The noxious effect of a given agent may be evident in one animal, non-existent in another species, even if the permeability of the placenta is similar in both cases.

Table III *Overall table (290 cases)*

ferent ways, descriptions based either on anatomopathology or on the type of deafness.

The arrival of a baby with a malformation of the ear is a *real family* tragedy and only the proposal of a precise therapeutic solution will ease the parents minds they will not be satisfied by a succession of examinations. It is above all necessary to give them precise information not only about the exact nature of the lesions, but also about the therapeutic timetable They must be reassured but they must also be told the truth without false promises. Much experience is necessary to make them agree to wait for a therapeutic answer in the distant future

There follows a few observations bearing these facts in mind.

A. The first principle of diagnosis

It is not possible to undertake a functional operation until the functional value of the ear is completely assessed.

Audiometric diagnosis is not simple it is generally submitted that a graph of free field conduction is not enough it gives only an overall picture of hearing and there may be surprises in store Before operating the otologist must know the curves of aerial and osseous conduction for each ear such a thing is not possible until the child is at least seven years old especially if only one ear is affected and it is necessary to use a technique of eliminating the hearing of the other ear The aim is to obtain accurate graphs.

Associated malformations of the outer and middle ear cause transmission deafness with an average loss of 60 dB over all frequencies it should not be forgotten that there is an audiometric and anatomopathological connection Two possibilities are described, with a clinical example (*a*) phantom curve (*b*) concomitant disorder of the inner ear

(a) Phantom curve

There are two types of phantom curve

The first type corresponds to a double phantom of the aerial and osseous curves. The ear is completely dead. The presence of total cophosis obviously affects treatment whether it is cophosis with normal contralateral ear or cophosis with disorder of the contralateral middle ear

The second type is that of the phantom of osseous conduction Deafness is not one of transmission but one of perception. This circumstance occurs as often in cases of major aplasia as in cases of supposed minor aplasia.

In all cases only vocal audiometry makes it possible to distinguish these different forms.

(b) Concomitant disorder of the inner ear

The two preceding examples have already involved the inner ear This might be suspected from radiograms, but the membranous cochlea is often isolated without any macroscopically apparent lesion When the difference of impedance is too small surgery is not the answer and a substitute method must be adopted.

Whatever the result of the audiometric examination it should be remembered that it must take its place alongside other factors. hereditary antecedents collateral and personal search for associated malformation of the cervical column the eye examination of the vestibule indicating by electrical perturbations a disorder of the membranous vestibule radiological examination simple radiogram and tomography neuropsychiatric examination giving intelligence quotient psychomotor retardation

Progress in speech is particularly interesting in cases of bilateral malformations The complete list makes it possible to ascertain the real cause or causes of retardation or lack of speech.

B. Therapy depends on whether the disorder is unilateral or bilateral

(a). Unilateral malformations

Minor malformation adolescence must be reached before surgery is performed.

Care is necessary since an abnormality of

necessary The major risk is the facial nerve. This argument has been stressed by certain authors who oppose surgery in the case of unilateral malformations. Others dispute the validity of operating to create a fenestra which might result in vertigo and difficulties when swimming.

The therapeutic calendar involves two dates, that of the functional stage in relation to the aesthetic stage. If an aesthetic stage is provided for care should be taken that the neo-pavillion is correctly placed in relation to the future external auditory canal. If the aesthetic stage is replaced by putting in place a prosthesis there is no problem.

The calendar specifies, above all, the date of the functional stage; it is not possible to operate until the child is seven for clinical and audiometric reasons as well as for surgical (the external auditory canal must be large).

It is advisable to judge the usefulness of the operation, when the controlateral ear is normal, according to the results. return to real binaural hearing is rare insistence on this fanciful idea must be abandoned, a persistent loss exists, but it is less than 30 dB the ear is then functional. A difference of impedance equal to and if possible inferior to 30 dB is the limit of tolerability If the otologist is sufficiently sure of the results, surgery is perfectly justified.

However the decision to operate is always influenced by psychological or social problems which are never negligible.

(b) Bilateral malformation

The rule about the age of seven is just as important in this case. Before seven, the child is equipped for osseous conduction and entrusted to a speech therapist so that he learns to speak in a suitable way After seven, functional surgery must be attempted, whether there are major or minor malformations, starting with the ear that is least deaf

Even partial closure of the difference of impedance is always helpful in these cases, it makes it possible to take away the apparatus from the ear

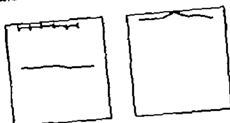

Fig. 13 Major malformation of outer ear Audiogram.

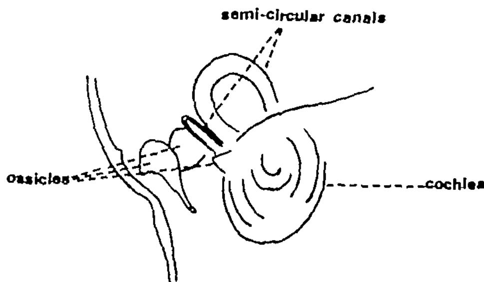
Fig 13 bis. Major malformation of middle and inner ear Audiogram.

The results of operations on malformations of the ear depend a great deal on the skill and the experience of the surgeon, but they are closely linked with the accuracy of the prescription of treatment.



II. PERCEPTIVE DEAFNESS WITHOUT APPARENT MALFORMATION

Without wishing to undertake a study of the treatment of deaf children here, it is useful to define the present tendencies in the education of young deaf children.

Scientific publications insist on the need to begin specialized education as early as possible, when the brain is at the stage of greatest development, so that the child learns to speak as normally as possible.

This presupposes, of course, that a diagnosis of deafness can be reached with certitude within the first few years: it is not our concern at present to discuss this very important aspect of the problem. It is necessary only to remember that the audiologist has the necessary means, whether he uses classic "acumetric" methods (squeaking toys,

Figs. II 1 Major malformation of outer ear Radiography

the facial nerve may put it in a vulnerable position There are various types of lesion

(*a*) blockage mesenchymatous remains or strips stapedo-vestibular ankylosis, blockage of the chain in two places.

(*b*) interruption absence of the malleus or the malleus reduced to just the manubrium malformation of the incus malformation of the stapes no ossicles.

(*c*) absence of fenestrae

Major malformation there are two aspects to be treated aesthetic and funtional

Aesthetic aspect Fashion plays an important part it has minimised the difference between the sexes. Attitude may depend on the results obtained. Is nothing at all preferable to a semblance of an ear? The question cannot be answered. A prosthesis gives excellent results as far as appearances are concerned but the patient sometimes prefers to keep his own ear even if it is ugly The family and especially the parents, also have their own opinion upon which they often insist.

Functional aspect The otologist has two objectives to put in place a vibrating surface at the end of a new external auditory canal and to re make the chain of ossicles after a complete examination of the tympanum.

Two or even three operations are sometime

necessary The major risk is the facial nerve. This argument has been stressed by certain authors who oppose surgery in the case of unilateral malformations. Others dispute the validity of operating to create a fenestra which might result in vertigo and difficulties when swimming.

The therapeutic calendar involves two dates, that of the functional stage in relation to the aesthetic stage. If an aesthetic stage is provided for care should be taken that the neo-pa ilion is correctly placed in relation to the future external auditory canal. If the aesthetic stage is replaced by putting in place a prosthesis there is no problem.

The calendar specifies, above all, the date of the functional stage, it is not possible to operate until the child is seven for clinical and audiometric reasons as well as for surgical (the external auditory canal must be large).

It is advisable to judge the usefulness of the operation, when the contralateral ear is normal, according to the results: return to real binaural hearing is rare, insistence on this fanciful idea must be abandoned, a persistent loss exists, but it is less than 30 dB the ear is then functional. A difference of impedance equal to and if possible inferior to 30 dB is the l mit of tolerability If the otologist is sufficiently sure of the results, surgery is perfectly justified.

However the decision to operate is always influenced by psychological or social problems which are never negligible.

(b) Bilateral malformation

The rule about the age of seven is just as important in this case Before seven, the child is equipped for osseous conduction and entrusted to a speech therapist so that he learns to speak in a suitable way After seven, functional surgery must be attempted, whether there are major or minor malformations, starting with the ear that is least deaf

E en partial closure of the difference of impedance is always helpful in these cases, it

makes it possible to take away the apparatus from the ear

The results of operations on malformations of the ear depend a great deal on the skill and the experience of the surgeon, but they are closely linked with the accuracy of the prescription of treatment.

II. PERCEPTIVE DEAFNESS WITHOUT APPARENT MALFORMATION

Without wishing to undertake a study of the treatment of deaf children here, it is useful to define the present tendencies in the education of young deaf children.

Scientific publications insist on the need to begin specialized education as early as possible, when the brain is at the stage of greatest development, so that the child learns to speak as normally as possible

This presupposes, of course, that a diagnosis of deafness can be reached with certitude within the first few years: it is not our concern at present to discuss this very important aspect of the problem. It is necessary only to remember that the audiologist has the necessary means, whether he uses classic acumetric" methods (squeaking toys,

screening test) which are still of value to a trained examiner or the excellent objective method of electro-encephalographic audiometry

It is interesting to analyse the solutions proposed for this early education. Before the child begins normal schooling, two periods can be defined schematically The first is from birth until the child is from two-and-a half to three years old, and the second from two-and-a half to three up to five or six, the age at which real schooling starts. The role of the family is fundamental in the education of a deaf child whatever its age at the time of diagnosis, but the first period is the one when the influence of the family is predominant This period is often called *mother and child education* The second period is that of the *nursery school*

A. Mother and-child education

Although it is an informal education no detail should be neglected. The meeting between the speech therapist and the mother and child should occur in a place that reminds the child of a normal home. The child is in natural surroundings, he can play have his meals, move about his mother watches him while going about her daily occupations. It is in these circumstances that the therapist comes in Meals and games are often chosen by the parents, who need specific much more than general guidance The behaviour of each child is closely examined on different occasions. It is assessed according to certain criteria and carefully noted However this analysis is complemented by a study of the attitude of the parents towards the child, in particular that of the mother This wonderful opportunity of observing both mother and child chould be used for one two or three days. Such close observation the assessment and recording of the facts observed are indispensable if valid advice is to be given to the parents. Furthermore this information must be in such a form that it may be used directly by all those who come into contact with or are in charge of the deaf child. This really scientific study of *the child* should make it possible with a certain margin of error to discover what kind of education will suit him best.

It is *not until after* this extremely long phase *of observation that* education begins. The speech therapist works in different fields, she *tries* to develop the attention and the visual *memory* to form judgement by classification exercises for example. She tries to draw the *child s attention* and interest towards the movements of the lips, *first of all by* breathing exercises, then by association with objects or situations. She develops the child s capacity for imitating movements of the body limbs, mouth tongue and lips. *All these exercises* are presented as games. The whole auditory education including the important part played by the initiation to rhythm is covered in these first game-exercises.

The frequency of sessions varies and depends on the distance and the availability The child stays in a specialized centre either for a day or for several days, with intervals of from fifteen days to a month

This is the way that mother and-child education is conducted at the Institut d Audiophonologie in Lyon. This solution can certainly be used in a large number of cases, but not in those where both the mother and father are at work There ought to be day-nurseries where the child could play under the supervision and with the help of a speech therapist the child would be taken there in the morning and taken back by his parents in the evening We find this solution less satisfactory than the first.

B. Nursery-schools for deaf children

When the child is older he may go to a nursery school If possible he is taken there, he plays and works for the morning or the whole day going home to his family every day Nursery-schools for the deaf have become quite customary Putting the child into a specialized centre for the deaf involves, in objective terms, the same dangers as boarding-

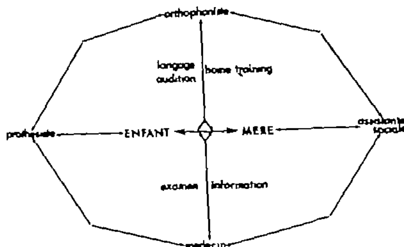

Fig. 14 Diagram of early identification and rehabilitation of young deaf children.

school. Ideally the child should enjoy the family atmosphere every day so that he remains in contact with his parents and brothers and sisters. A specialized nursery-school for the deaf is only possible in a large town for families in rural areas and small towns the problems are complex and the best use must be made of mother-and-child education in the centre up to nursery-school age, between periods of specialized education the child goes to an ordinary nursery-school.

It is the contact between the therapist and the child and his mother that makes it possible to fit into the most ordinary of daily acts the introduction of the child to language to human communication. Hearing aids are included in this rehabilitation. This is possible since modern audiometric methods are improving all the time and the auditory loss can be diagnosed with great accuracy When the exact auditory loss is known and informal and, in particular auditory education has begun a hearing aid can be considered as early as possible according to the preceding conditions.

It must not be pretended that the education of a deaf child depends on early education alone. There are fundamental factors over which the doctor and the therapist have no control. The intelligence quotient is very important. The higher it is, the easier is the child's education. The profundity of deafness is also, in our opinion very important. The profoundly deaf child is one whose handicap is greatest to overcome. This child benefits greatly from early education, even from early use of a hearing aid, but the result will not be as good as when there is only partial deafness which responds better to aids. The best results are still achieved in cases of partial deafness. In these circumstances early education gives the most spectacular results, in fact the child may be able to go to an ordinary school and follow under medical and therapeutic control, a perfectly normal education.

Summary

As far as the aetiology of deafness in children is concerned, the pathology of pregnancy is a field which is still relatively unexplored although it is of capital importance when considering the prophylaxis of the problem.

Embryological data shows that although the

ear is anatomically constituted by the end of the third month of pregnancy histological modifications continue until the sixth month and the histochemical evolution perhaps continues even well beyond that

It is difficult therefore to consider separately auricular embryopathies and foetopathies, especially since the same pathological agent may intervene at either the embryo stage or the foetal stage.

Different factors are liable to damage the ear or to perturb its development before birth

Of the *infectious causes* the rubella virus holds first place its form of action the different clinical aspects of the rubella embryopathy are now well known

Other viral or microbic agents such as measles mumps, influenza shingles pneumococci, streptococci etc that is, they are probable causes which cannot yet be definitely confirmed

In the case of *gravidic parasitosis* the danger toxoplasma represents to the foetus must be stressed. The effect on the ear of congenital toxoplasmosis has been described only recently but it is likely that this aspect will become very important in future

Ionising radiation has for a long time been suspected of having a teratological effect but little has been published on the elective affections of the ear

The study of embryopathies and foetopathies of toxic origin—whether the noxious substance be exogenic, medicamentous in particular or endogenous—has recently become of great and immediate interest as a result of the dramatic consequences of the use of Thalidomide.

Because of the continued presence of many unknown factors in this field, it is difficult to provide general rules for prophylaxis at present the centralization of observations and experiments with animals will undoubtedly lead to progress in the future.

In practice the preventive measures at the disposal of the clinician are caution in the administration of medicamentous treatment to pregnant women vaccination against rubella and close supervision of labour to prevent the possible aggravation of lesions by anoxia.

All too often it is possible only to treat a child already malformed or suffering from deafness to a greater or lesser extent. The fundamental principles then guiding the otologist are early education of the young deaf child at first within the family and later in a specialized nursery school information indicating whether the subject is unilaterally or bilaterally affected in the case of auricular malformation

Zusammenfassung

Der Einfluss verschiedener Krankheiten während der Schwangerschaft auf angeborene Schwerhörigkeit oder Gehörlosigkeit bei Kindern ist ein noch wenig erforschtes Kapitel, obwohl es von prophylaktischem Standpunkt aus gesehen ungeheuer wichtig ist

Die embryonale Entwicklungsgeschichte zeigt dass die anatomischen Ansätze des Gehörorganes am Ende des dritten Schwangerschaftsmonats ausgebildet sind dass sich aber die histologischen Veränderungen bis zum sechsten Schwangerschaftsmonat hinausziehen und die histo-chemischen Prozesse noch länger bis zu ihrer Vollendung brauchen

Es ist daher schwierig, genau zwischen Embryopathien und Foetopathien zu unterscheiden zumal die verschiedenen Krankheitserreger während beider Entwicklungsperioden

wirken können. Verschiedene Faktoren können das Gehörorgan während seiner Entwicklung zerstören oder hemmen.

Viren und Bakterien

Der Rotel-Virus (rubeolis) nimmt eine Vorzugsstellung ein. Seine Wirkungsweise, die verschiedenen klinischen Aspekte und die verursachten Embryopathien sind jetzt gut bekannt. Andere Viren und Bakterien sind genannt worden: Virus der Masern, des Mumps, der Grippe und auch Pneumococcus, Streptococcus ... Es handelt sich bei den Letzteren um mögliche aber nicht bestätigte Ursachen.

Parasiten

Es soll unterstrichen werden, dass der Krankheitserreger der Toxoplasmose Einfluss auf die Entwicklung des Gehörorganes nimmt. Die angeborene Toxoplasmose des Gehörorganes ist bisher wenig beschrieben worden, aber es scheint, dass diese Ursache in Zukunft naher in Betracht zu ziehen ist.

Strahleneinwirkung

Die Vermutung, dass ionisierende Strahlen Ursache von Missbildungen am Gehörorgan sein können, ist schon lange aufgestellt worden. Man findet aber wenige Dokumente in der Literatur, dass diese isolierten Schäden am Gehörorgan verursachen.

Endogene und Exogene Vergiftungen

Das Studium dieses Kapitels hat nach den traurigen Ereignissen infolge Gebrauchs von Kontergan bei schwangeren Frauen an Wichtigkeit gewonnen. Neben den exogenen Ursachen, bei denen die Medikamente eine Sonderstellung einnehmen, können auch endogene Vergiftungsursachen erwogen werden.

Leider bestehen auf diesem Gebiete noch viele Unklarheiten und man kann kaum prophylaktische Ratschläge geben. Vielleicht ermöglicht eine zentrale Auswertung der klinischen Fälle und der Tierexperimente baldige Fortschritte. Bis auf weiteres kann der Kliniker nur Vorsicht beim Gebrauch von Medikamenten bei Schwangeren walten lassen, Impfung gegen Röteln zum gegebenen Zeitpunkt vornehmen und die Ursachen des Sauerstoffmangels während der Entbindung bekämpfen, um eventuell schon bestehende Schäden nicht noch zu erschweren.

Leider steht der Kliniker aber noch oft den Schäden am Gehörorgan auf dem therapeutischen Stadium gegenüber und es handelt sich darum, sich mit einem missgebildeten, mehr oder weniger schwerhörigen Kind zu befassen. Einige Grundsätze leiten dann den Spezialisten. Frühzeitige Erziehung des Schwerhörigen — erst im Familienkreise und dann in Sondereinrichtungen, Wahl unter verschiedenen Behandlungsmethoden je nachdem ob die Schwerhörigkeit nur eine oder beide Seiten betrifft.

Resumé

La pathologie de la grossesse représente un chapitre encore assez mal exploré dans l'étiologie des surdités de l'enfant et cependant d'une importance capitale, si l'on considère l'aspect prophylactique du problème.

Les données embryologiques montrent que si l'oreille est anatomiquement constituée dès la fin du troisième mois de la grossesse, des modifications histologiques se poursuivent jusqu'au sixième mois, et peut-être même l'évolution histochimique se poursuit-elle bien au-delà.

Résumé

La pathologie de la grossesse représente un chapitre encore assez mal exploré dans l'étiologie des surdités de l'enfant et cependant d'une importance capitale si l'on considère l'aspect prophylactique du problème.

Les donnees embryologiques montrent que si l'oreille est anatomiquement constituée dès la fin du troisième mois de la grossesse, des modifications histologiques se poursuivent jusqu'au sixième mois, et peut-être même l'evolution histochimique se poursuit-elle bien au-delà.

Il est donc difficile d'envisager de façon distincte les embryopathies et les foetopathies auriculaires, d'autant plus qu'un même agent pathologique peut intervenir aussi bien pen-

dant la période embryologique que pendant la période foetale

Différents facteurs sont susceptibles de léser l'oreille ou d'en perturber le développement pendant la vie intra utérine

Parmi les *causes infectieuses* le virus de la rubéole tient la première place ses modalités d'action, les différents aspects cliniques de l'embryopathie rubéolique sont maintenant bien connus.

D'autres agents viraux ou microbiens sont également incriminés tels ceux de la rougeole, des *oreillons*, de la grippe du zona ou encore pneumocoque streptocoque etc. il s'agit pour l'*instant* de causes probables que l'on ne peut affirmer avec certitude

Il faut souligner dans le cas des *parasitoses gravidiques* le risque que fait courir au foetus le toxoplasme. L'atteinte auriculaire de la *toxoplasmose* congénitale a été décrite depuis peu mais il semble que cette étiologie soit appelée à prendre une place importante

Les *radiations ionisantes* sont depuis long temps soupçonnées d'une action tératologique mais la littérature reste assez pauvre en ce qui concerne les atteintes électives de l'oreille

Quant aux embryopathies ou foetopathies d'*origine toxique* — la substance nocive pouvant être exogène, médicamenteuse surtout, ou endogène — leur étude a pris une actualité et une importance majeure à la suite des dramatiques conséquences de l'utilisation de la Thalidomide.

Du *fait des nombreuses inconnues* persistant à l'heure actuelle dans ce domaine il est difficile de définir les règles prophylactiques générales centralisation des observations, expérimentations chez l'animal permettront, sans nul doute des progrès futurs.

En pratique, prudence dans le maniement des thérapeutiques médicamenteuses chez la femme enceinte vaccination contre la rubéole, surveillance étroite de l'accouchement pour éviter l'aggravation des lésions par une éventuelle anoxie représentent les mesures préventives essentielles à la disposition du clinicien.

Trop souvent encore c'est au stade thérapeutique qu'il faut agir devant un enfant malformé ou porteur d'une surdité plus ou moins sévère Quelques principes fondamentaux doivent alors guider l'otologiste éducation précoce du jeune enfant sourd dans sa famille d'abord, puis dans un jardin d'enfants spécialisé indications centrées sur l'uni- ou la bi-latéralité de l'atteinte dans le cas de malformations auriculaires.

Introduction

The study of the transport of ions and molecules across Reissner's membrane is important for understanding the origin and circulation of the labyrinthine fluids. The first evidence of transport of ions across this membrane was obtained by Rauch, Köstlin, Schneider & Schindler (1963) who injected ^{24}Na and ^{42}K compounds in the perilymph and measured the concentration of labelled ions in both endolymph and perilymph. ^{42}K and ^{24}Na crossed Reissner's membrane from perilymph to endolymph, but the concentration of ^{42}K in the endolymph was about five to eight times greater than Na. When injecting enzyme blocks, either iodo acetate, sodium cyanide or strophanthin G into the perilymphatic space prior to injecting ^{42}K and Na, the radioactivity of the endolymph was reduced by approximately two-thirds the amount previously measured. By means of these biochemical methods they concluded that Reissner's membrane actively transports ions from perilymph toward endolymph.

Ilberg (1968) has provided morphological evidence of a transport mechanism across Reissner's membrane. He injected a colloidal suspension of thorium dioxide into the perilymphatic or endolymphatic space as a marker. This substance crossed Reissner's membrane in both directions by a combination of diffusion and active transport mechanisms. He also reported when remaining in the cochlear duct for more than 30 minutes, thorium dioxide produced toxic changes in the cells of Reissner's membrane.

Several aspects of Ilberg's important work led us to reinvestigate the transport mechanism across Reissner's membrane. Firstly the possibility arose that the toxicity of thorium dioxide may have altered the transport of macromolecules across Reissner's membrane. Hence, it seems advisable to study this process by means of a different substance, namely ferritin, which is more biological and less toxic electron-opaque tracer. A second aspect we considered was that injection of a substance in either space may rupture Reissner's membrane resulting in a mixture of endolymph and perilymph and thereby contaminating both fluids with the tracer. When this occurs the amplitude of the cochlear potentials decreases significantly (Davis et al., 1955, Lawrence et al., 1961). The endocochlear potential (EP) provides an excellent indicator of the Reissner's membrane integrity. It can be monitored by means of a microelectrode inserted in the endolymph and in absence of acoustic stimulation its value is about 80 millivolts positive relative to the perilymph and the tissue fluids generally. A third point is that fixation of the tissue by immersion is inadequate because all the cochlear structures are surrounded by bone with only narrow channels for diffusion of the fixative. Thus a fixation in vivo by perfusion of the fixative through scala tympani and with an outlet in scala vestibuli or vice versa is necessary.

For the reasons stated above, we investigated the transport of macromolecules across Reissner's membrane using ferritin as electron-opaque tracer. The integrity of Reissner's membrane was monitored through EP recording during and after injection of ferritin in the labyrinthine spaces. Adequate fixation of Reissner's membrane was accomplished by intracochlear perfusion of the fixative *in vivo*.

Our data indicate that transport of ferritin takes place across Reissner's membrane from the perilymph toward the endolymph but not in the opposite direction.

Introduction

The study of the transport of ions and molecules across Reissner's membrane is important for understanding the origin and circulation of the labyrinthine fluids. The first evidence of transport of ions across this membrane was obtained by Rauch, Köstlin, Schneider & Schindler (1963) who injected ^{24}Na and ^{42}K compounds in the perilymph and measured the concentration of labelled ions in both endolymph and perilymph. ^{42}K and ^{24}Na crossed Reissner's membrane from perilymph to endolymph, but the concentration of ^{42}K in the endolymph was about five to eight times greater than Na. When injecting enzyme blocks, either iodo acetate, sodium cyanide or strophanthin G into the perilymphatic space prior to injecting ^{42}K and Na, the radioactivity of the endolymph was reduced by approximately two-thirds the amount previously measured. By means of these biochemical methods they concluded that Reissner's membrane actively transports ions from perilymph toward endolymph.

Ilberg (1968) has provided morphological evidence of a transport mechanism across Reissner's membrane. He injected a colloidal suspension of thorium dioxide into the perilymphatic or endolymphatic space as a marker. This substance crossed Reissner's membrane in both directions by a combination of diffusion and active transport mechanisms. He also reported when remaining in the cochlear duct for more than 30 minutes, thorium dioxide, produced toxic changes in the cells of Reissner's membrane.

Several aspects of Ilberg's important work led us to reinvestigate the transport mechanism across Reissner's membrane. Firstly the possibility arose that the toxicity of thorium dioxide may have altered the transport of macromolecules across Reissner's membrane. Hence, it seems advisable to study this process by means of a different substance, namely ferritin, which is more biological and less toxic electron-opaque tracer. A second aspect we considered was that injection of a substance in either space may rupture Reissner's membrane resulting in a mixture of endolymph and perilymph and thereby contaminating both fluids with the tracer. When this occurs the amplitude of the cochlear potentials decreases significantly (Davis et al., 1955; Lawrence et al., 1961). The endocochlear potential (EP) provides an excellent indicator of the Reissner's membrane integrity. It can be monitored by means of a microelectrode inserted in the endolymph and in absence of acoustic stimulation its value is about 80 millivolts positive relative to the perilymph and the tissue fluids generally. A third point is that fixation of the tissue by immersion is inadequate because all the cochlear structures are surrounded by bone with only narrow channels for diffusion of the fixative. Thus a fixation in vivo by perfusion of the fixative through scala tympani and with an outlet in scala vestibuli or vice versa is necessary.

For the reasons stated above, we investigated the transport of macromolecules across Reissner's membrane using ferritin as electron-opaque tracer. The integrity of Reissner's membrane was monitored through EP recording during and after injection of ferritin in the labyrinthine spaces. Adequate fixation of Reissner's membrane was accomplished by intracochlear perfusion of the fixative *in vivo*.

Our data indicate that transport of ferritin takes place across Reissner's membrane from the perilymph toward the endolymph but not in the opposite direction.

Materials and Methods

The experiments were carried out in a series of 22 healthy adult cats of which 5 serve as controls. Each animal was anesthetized with intraperitoneal pentobarbital sodium (0 6 ml per kg of body weight) Tracheotomy was per formed and the cat s head was fixed rigidly in a restraining device until no respiratory displacements could be observed under high amplification of a dissecting microscope A retroauricular approach to the middle ear was carried out exposing the round window niche.

Technique for endolymphatic injection of ferritin

Two glass pipettes were mounted side by side on a micromanipulator One whose diameter at the tip was about 8 μ contained an estimated volume of 0 10 to 0.33 μl of ferritin solution This pipette was connected by a polyethylene tube to a hydraulic microdrive. The other pipette whose tip diameter was about 2 μ was filled with 3 M NaCl or 0 1 M KCl

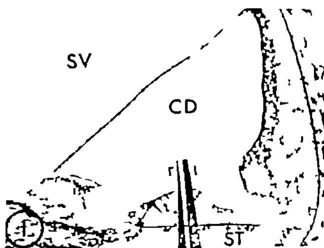

Fig 1 Photomicrograph of the cochlear duct of the cat showing an outlin f two pipettes, one for re cording endocochlear potential ( ), and the other for injection of ferritin in the cochlear duct (*i*). it was used for simultaneous recording of the endocochlear potential (EP).

The membrane covering the round window was removed, thus permitting adequate visual observation of the basilar membrane. With the aid of a high power dissecting microscope the basilar membrane was impaled at the level of the Claudius cells and about 3 mm from the base of the cochlea. The pipettes were advanced slowly until the recording mic ropipette recorded a positive EP of about 80 mV indicating that the tips of the pipettes were in the cochlear duct (Fig. 1) The endocochlear potential was recorded by an elec trometer (E–H Research Laboratories, Model 250) and registered on an Offner Dynograph. The ferritin solution was then slowly injected throughout a 1 to 2 minute interval. After completion of the injection an approximately equal volume of endolymph was withdrawn The elapsed time between completion of fer ritin injection and intravital fixation of the cochlea was 10 20 30 60 or 120 min during which time the EP was recorded during the first 5 min following ferritin injection.

Technique for perilymphatic injection of ferritin

A glass pipette, 150–250 μ inside diameter at the tip was mounted on a micromanipula tor and connected by means of a polyethylene tube to a syringe containing 2 cc of ferritin solution the syringe was placed on a Harvard infusion withdrawal pump The pipette was filled to the tip with ferritin solution, thus eliminating all bubbles. The pipette was then gently introduced through the round window membrane into the scala tympani The stapes was removed and the ferritin solution was in jected at a rate of 0.68 ml per minute for approximately 3 min After an interval of

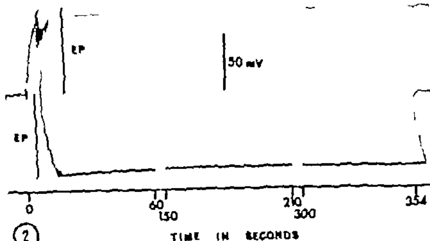

Fig 2 Cat Fe-19 Record of negative potential (EP^- – 80 mV) within the organ of Corti and positive endocochlear potential (EP^+ 76 mV) within the cochlear duct. After penetrating the cochlear duct, EP^+ exhibited slow progressive decay (6 mV) reaching a steady state in one minute. Injection of ferritin into scala media (time of injection indicated by two arrow heads) apparently was not associated with changes in the course of EP^+ Calibration marker – 50 mV

from 60 to 120 min, intravital fixation of the cochlea was carried out.

To prevent interference with EP recording during perilymphatic injection, the pipette containing ferritin was introduced through the footplate of the stapes into the vestibule, thus the injection was from scala vestibuli toward scala tympani. The pipette for recording EP and the technique for introducing it into cochlear duct was similar to that described for endolymphatic injection (Fig 3). Again the EP was recorded for 5 min after ferritin injection.

Preparation of ferritin stock solutions

Horse spleen cadmium-free ferritin (1 gm in 10 ml) was obtained from Nutritional Biochemicals Corp. (Cleveland, Ohio). Commercial cadmium-free" ferritin contains traces of the cadmium sulphate used for crystallization of the protein (Eybl & Ryser 1964). In order to remove these toxic traces, the ferritin solution was dialysed at 2 C for 72 hours against three changes of 3.7% disodium dihydrogen versenate (EDTA) in 0.15 M phosphate buffer at pH 7.0, followed by additional dialysis for three days against three changes of Gey s balanced salt solution at 2 C (Farquhar & Palade, 1961). The ferritin solution was then tested for the presence of cadmium following the method of Granick (1942).

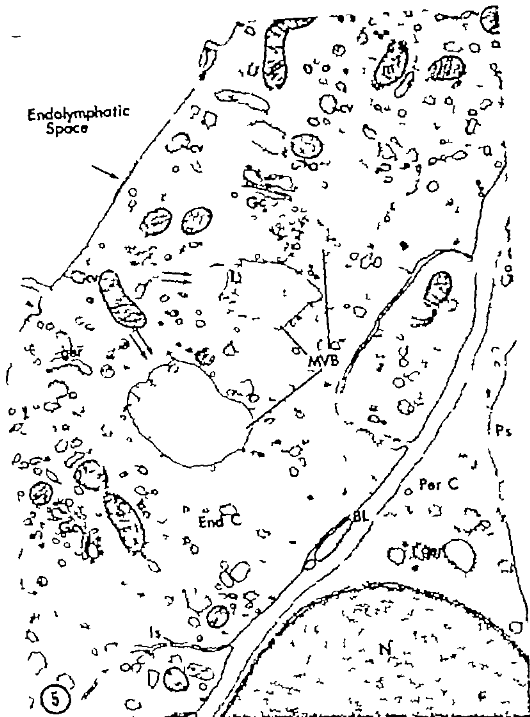

Fig. 5. Low power electron micrograph of Reissner membrane 30 min after injection of ferritin in the endolymph. Ferritin molecules are seen adhering to localized area of filamentous coating of the outer surface of the membrane (*arrow*). The tracer is also visible in vesicular invagination (*arrow head*) of the free surface of the endolymphatic cell and in coated vesicles (*cv*). The latter are accumulated near the free surface of the cell. Three multivesicular bodies containing ferritin molecules are seen in different stages of development. These bodies are surrounded by numerous round vesicles. A localized dense material is seen in the cytoplasmic side of the membrane of two multivesicular bodies (*double arrow*). This material is projected for a variable distance into the cytoplasm. No ferritin molecules were found in the intercellular space, basal lamina or in the perilymphatic cell. 3 085

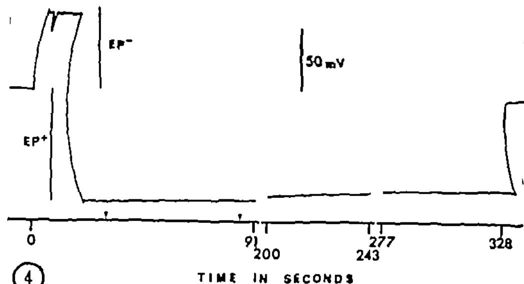

Fig 4 Cat Fe 7 Record of the endocochlear potentials after injection of ferritin in the perilymph. The negative potential (EP^-) within the organ of Corti was 60 mV and the positive endocochlear potential (EP) was 90 mV EP exhibited slow progressive decay of about 14 mV in 5 min Time of injection of ferritin is indicated by two arrow heads. Calibration marker = 50 mV

The ferritin solution was sterilized by passing it through a 0 45 μ mesh Millipore filter The filtrate was received in covered sterile ampules which were immediately refrigerated. The concentration of ferritin was estimated to be approximately 100–125 mg/ml in the sterile solution

Technique for intravital fixation of the cochlea[1] and subsequent treatment

The intravital fixation of the cochlea and subsequent treatment were done identically in the experimental animals and controls. A glass pipette of 150–250 μ inside diameter at the tip was mounted on a micromanipulator The pipette was connected through a polyethylene tube to a syringe containing 30 0 cc of 2.67% solution of osmium tetroxide in s-Collidine buffer at pH 7 4 (Bennett & Luft 1959). To maintain the temperature of the fixative at about 4 C during perfusion of the cochlea the syringe was mounted in a copper container filled with ice The syringe and the copper container were placed on a Harvard infusion/withdrawal pump this instrumentation being ready for immediate use after completing ferritin injection

After removal of the pipettes used for the endolymphatic injection of ferritin and EP recording, the oval window was exposed and both crurae of the stapes were removed. The pipette used for perfusion was first completely filled with fixative to eliminate all bubbles. Then it was introduced gently through the footplate of the stapes into the vestibule and the pump was activated The fixative was flowed through the scala vestibuli scala tympani and out through the round window being gently sucked from the middle ear cavity Direct observation of both round and oval windows showed that most of the fixative flowed out of the round window although some fluid seepage between the pipette and the borders of the perforation in the footplate of the stapes was noticed. The perfusion rate was 1 23 ml per minute hence the total perfusion time was about 24–25 min

In the case of perilymphatic injection of

[1] This technique was published in a preliminary form in Hinojosa R & Rodriguez Echandia, E. L. 1966 The fine structure of the stria vascularis of the cat inner ear *Am r J Anat 118*, 631

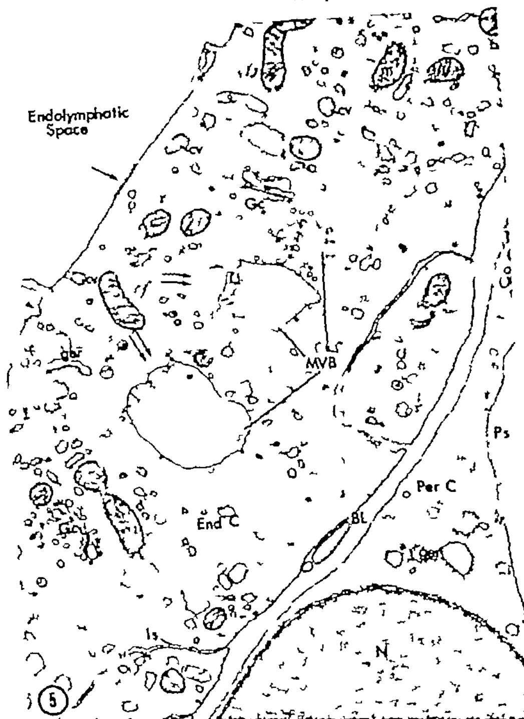

Fig. 5. Low power electron micrograph of Reissner's membrane 30 min after injection of ferritin in the endolymph. ferritin the pipette and polyethylene tube used for injection of the marker were kept in place but the syringe was replaced with a 30.0 cc syringe containing fixative. The fixative flowed from scala tympani into scala vestibuli and out through oval window. In some animals the flow direction was reversed.

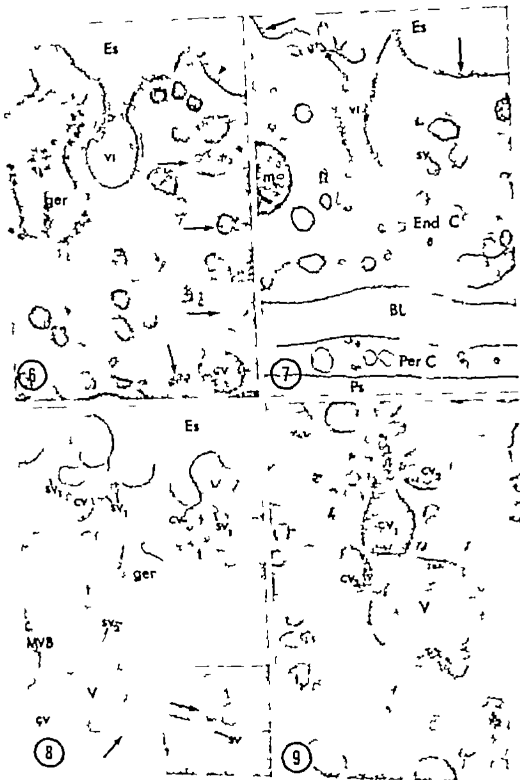
Upon completion of perfusion the anesthetized animal was decapitated and the cochlea removed from the temporal bone. Under a dissecting microscope, the lateral wall of the otic capsule was removed rapidly with a fine chisel and the cochlea immersed in the fixative for 3 1/2 hours. After fixation the specimen was transferred to cold 70% ethanol and the cochlear was partitioned under a dissecting microscope into a number of small pieces. The specimens were dehydrated in increasing concentrations of ethanol and then embedded in Epon 812 according to Luft (1961).

Sections were obtained with an LKB Ultrotome III equipped with a diamond knife collected on copper grids covered with carbon film (Robertson, 1959) and stained with lead tartrate (Millonig, 1961) or lead citrate (Reynolds, 1963). The sections were examined and photographed in a Philips EM 300 Electron Microscope operated at 40 kV. Thick sections of about 1 μ were cut with a glass knife mounted on slides and covered with immersion oil under a coverslip. These sections were examined with phase contrast under a Zeiss Photo-microscope.

Observations



The ultrastructure of Reissner's membrane has been fully described in the literature (Hagiwara, 1963; Duvall & Rhodes, 1967; Iurato 1967; Iurato & Taidelli, 1967) thus a short summary of the most important features related to our work is here included. Reissner's membrane separates the endolymphatic from the perilymphatic space. The membrane is a thin epithelium which varies from 1.2 μ to 3.3 μ in thickness, it consists

Fig. 6. An area of an endolymphatic cell fixed 1 hour after injection of ferritin in the endolymph showing a vesicular invagination of the free surface (vi) with numerous ferritin molecules which are apparently attached to the external filamentous coating of the membrane. The cytoplasmic side of this vesicular invagination is covered with thin radially striated layer. A localized area of the plasmalemma shows an external filamentous coating to which few ferritin molecules are apparently attached (*arrow head*). Ferritin molecules are also seen in small vesicles (*arrows*) and in a coated vesicle (*cv*). 80.556.

Fig. 7. Reissner's membrane 1 hour after injection of ferritin in the endolymph showing a portion of an endolymphatic cell, basal lamina and perilymphatic cell. Ferritin molecules are apparently adherent to areas of external coating of the cell membrane (*arrow*). Numerous molecules of the tracer are seen in a channel-like tubular invagination (*t*) of the plasmalemma. A small vesicle (*v*) with a single ferritin molecule is found in the cytoplasm. No tracer molecules are found in either the basal lamina or perilymphatic cell. 44 893.

Fig. 8. A portion of an endolymphatic cell 1 hour after injection of ferritin in the endolymph. The tracer is found in small vesicles (*sv1*), coated vesicles (*cv*), tubular structures (*t*) and in other small vesicles (*sv2*) located near a vacuole (*V*) which also contains ferritin. A small vesicular profile (*arrow*) seems to be fused with or budding from the vacuole (*V*). The diameter of the small vesicles is 650-750 Å. *Inset*. This micrograph shows a small vesicular invagination (*arrow*) of the free surface of a microvillus. The cell membrane shows, at the left of the inset, a localized area of external filamentous coating in which few ferritin molecules are apparently attached. 53 35... *Inset* 82 080.

Fig. 9. An area near the free surface of an endolymphatic cell 30 min after injection of ferritin in the endolymph. A coated vesicle (*cv*) continuous with a tubular structure contains ferritin molecules. Both the coated vesicle (*cv*) and the tubular structure exhibit a continuous inner coating but notice the difference in density of their lumen. The tracer also appears in other coated vesicles (*cv*), a vacuole (*V*) and in some irregular tubular structures (*t*). Another tubular structure (*t1*) with a bulb-like dilatation also contains numerous ferritin molecules. 74 898.

ferritin the pipette and polyethylene tube used for injection of the marker were kept in place but the syringe was replaced with a 30.0 cc syringe containing fixative. The fixative flowed from scala tympani into scala vestibuli and out through oval window In some animals the flow direction was reversed.

Upon completion of perfusion the anesthetized animal was decapitated and the cochlea removed from the temporal bone. Under a dissecting microscope the lateral wall of the otic capsule was removed rapidly with a fine chisel and the cochlea immersed in the fixative for 3 1/2 hours. After fixation the specimen was transferred to cold 70% ethanol and the cochlear was partitioned under a dissecting microscope into a number of small pieces. The specimens were dehydrated in increasing concentrations of ethanol and then embedded in Epon 812 according to Luft (1961).

Sections were obtained with an LKB Ultrotome III equipped with a diamond knife collected on copper grids covered with carbon film (Robertson 1959) and stained with lead tartrate (Millonig 1961) or lead citrate (Reynolds, 1963) The sections were examined and photographed in a *Philips EM 300* Electron Microscope operated at 40 kV Thick sections of about 1 μ were cut with a glass knife mounted on slides and covered with immersion oil under a coverslip. These sections were examined with phase contrast under a Zeiss Photo-microscope

Observations

The ultrastructure of Reissner's membrane has been fully described in the literature (Hagiwara, 1963 Duvall & Rhodes, 1967 Iurato 1967 Iurato & Taidelli, 1967) thus a short summary of the most important features related to our work is here included. Reissner's membrane separates the endolymphatic from the perilymphatic space. The membrane is a thin epithelium which varies from 1 2 μ to 3 3 μ in thickness it consists

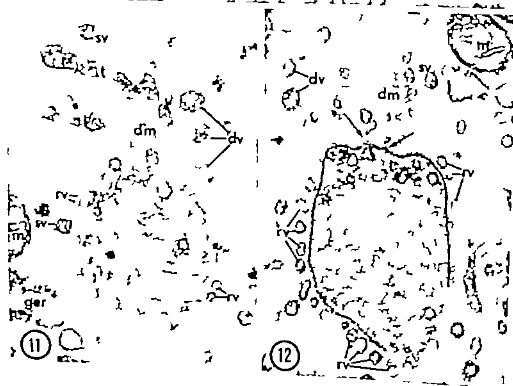

Fig 6 An area of an endolymphatic cell fixed 1 hour after injection of ferritin in the endolymph showing a vesicular invagination of the free surface (vI) with numerous ferritin molecules which are apparently attached to the external filamentous coating of the membrane. The cytoplasmic side of this vesicular invagination is covered with thin radially striated layer A localized area of the plasmalemma shows an external filamentous coating to which few ferritin molecules are apparently attached (*arrow head*). Ferritin molecules are also seen in small vesicles (*arrows*) and in a coated vesicle (*cv*). 80 256.

Fig 7 Reissner's membrane 1 hour after injection of ferritin in the endolymph showing a portion of an endolymphatic cell basal lamina, and perilymphatic cell Ferritin molecules are apparently adherent to areas of external coating of the cell membrane (*arrows*) Numerous molecules of the tracer are seen in a channel-like vesicular invagination (*I*) of the plasmalemma. A small vesicle (*sv*) with a single ferritin molecule is found in the cytoplasm. No tracer molecules are found in either the basal lamina or perilymphatic cell. 44 893

Fig 8 A portion of an endolymphatic cell 1 hour after injection of ferritin in the endolymph. The tracer is found in small vesicles (*v1*), coated vesicles (*cv*), tubular structures (*t*) and in other small vesicles (v_2) located near a vacuole (*V*) which also contains ferritin. A small vesicular profile (*arrow*) seems to be fused with or budding from the vacuole (*V*). The diameter of the small vesicles is 650–750 Å. *Inset* This micrograph shows a small vesicular invagination (*arrow*) of the free surface of a microvillus. The cell membrane shows, at the left of the inset, a localized area of external filamentous coating in which few ferritin molecules are apparently attached 53 35.. *Inset* 82 080

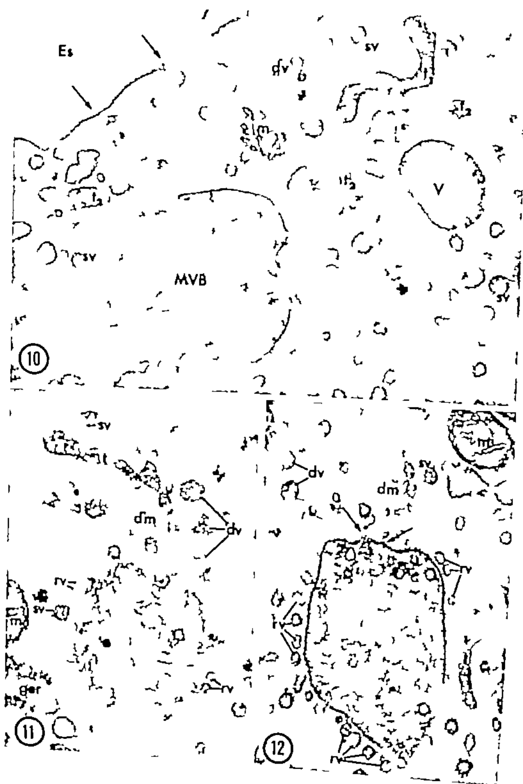
of two layers of cells which can be distinguished by their shape location and cytoplasmic characteristics. A distinct basal lamina (basement membrane) is found between the two cellular layers. The cells facing the endolymphatic space referred to as endolymphatic cells, are low cuboidal and their free surface shows numerous short microvilli. Our control material also showed that the microvilli contained small uncoated vesicles which vary in number from one microvillus to another The cell membrane measures 90 Å in thickness and shows numerous vesicular invaginations from which coated vesicles are formed Both types of vesicles, small vesicles and coated vesicles, accumulate in the apical cytoplasm. Numerous multivesicular bodies, vacuoles, mitochondria granular endoplasmic reticulum and elements of the Golgi complex are found dispersed throughout the cytoplasm. Adjacent cells are attached by typical junctional complexes consisting of a zonula occludens, zonula adherens and a macula adherens or desmosome. The lower third of the lateral plasmalemma characteristically follows a meandering course Adjacent endolymphatic cells are separated by a 150 to 200 Å intercellular cleft. The perilymphatic cells, i.e those facing the perilymphatic space are thin and elongated. The relatively few organelles, contained in these cells are located mainly around the nucleus. Small uncoated vesicles are found distributed all along the cytoplasm. The margins of adjoining perilymphatic cells either abut bluntly or overlap (Fig 17) in either case there is a simple junctional complex consisting of regions of simple apposition of the unit membranes (Fig. 17) The basal lamina is a continuous layer of apparently amorphous material 300 to 500 Å in thickness it follows the small irregularities of the basal plasmalemma of the endolymphatic cells.

Endolymphatic Injection



While advancing the micropipette through the organ of Corti two potentials were found. First as the recording pipette penetrated the basilar membrane into the organ of Corti, a negative potential (EP) of about 80 mV was

---

Fig 10 A portion of an endolymphatic cell, 30 min after injection of ferritin in the endolymph, showing ferritin molecules closely apposed to localized areas of external coating of the free surface of the cell (*arrows*). An irregular tubular structure (*t*), with dense lumen, contains numerous ferritin molecules which are mainly accumulated in the bulb-like dilatations. The tracer also appears in other tubular structures (t_1), and in the lumen of both a vacuole (*V*) and a *multivesicular body* Notice in the last two organelles an inner filamentous coating of their limiting membrane in which numerous ferritin molecules are apparently embedded. Notice also that in the lumen of the multivesicular body the ferritin molecules tend to be distributed in a linear pattern. A dense round structure (*dr*), which apparently presents no limiting membrane, contains few ferritin molecules. The tracer also appears in dense small vesicles (*s*) of about 900 Å in diameter 58 48…

Fig 11 Multivesicular body in an endolymphatic cell two hours after injection of ferritin into the endolymph It shows accumulation of dense material (*dm*) at one pole of the body A tubular structure (*t*) and few vesicular profiles, *some of them with ferritin molecules are surrounded by dense material* (*dm*). Few small vesicles (*n*) and dense vesicles (*d*), all containing ferritin, are seen close to the multivesicular body which shows numerous ferritin molecules. A few round vesicles (*rv*) are seen near the multivesicular body 60 534

Fig 12 Multivesicular body of an endolymphatic cell, 30 min after injection of ferritin in the endolymph. One pole of the body shows accumulation of dense material (*dm*) in which numerous vesicular profiles are included. Some of these vesicles contain ferritin molecules. The vesicular profiles tend to be grouped in rows which are oriented along the dense material (*dm*). Two of these vesicular profiles (*arrows*) containing ferritin molecules seem to be fused with the membrane of the multivesicular body This organelle shows numerous vesicles which are mainly concentrated in the upper pole. The tracer is found abundantly in the lumen of the multivesicular body. Notice that the tracer is accumulated in small clusters around the inner vesicles but no ferritin molecules are found within the vesicles. Numerous round vesicles (*rv*) without ferritin molecules, are seen adjacent to the membrane of the multivesicular body The tracer appears in dense vesicles (*dv*) small vesicles ( ) and in tubular structure (*t*) located near the multivesicular body 5 3 6

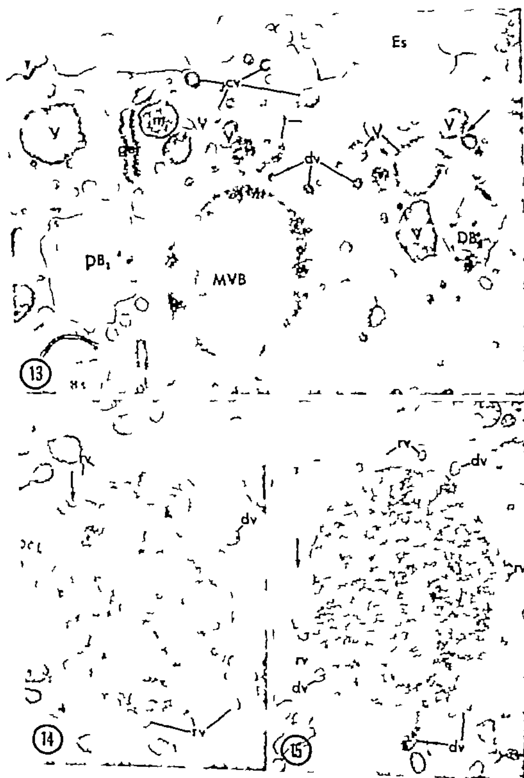
recorded (Fig. 2). The nature of this potential is still a subject of controversy (Békésy 1952 Butler 1965 Lawrence, 1967) Second when the micropipette impaled the cochlear duct the potential changed polarity (EP) that is the endolymph became positive relative to the reference point in the neck muscle (Békésy 1952) This potential probably is generated by metabolic activity in the stria vascularis (Davis et al. 1958 Tasaki & Spyropoulos, 1959) As shown in Fig 2, the amplitude of EP decayed slowly and progressively in the course of about 5 min from an original value of 76 mV to 70 mV Control experiments without injection of ferritin showed similar decay suggesting that this may be due to factors other than injection of the tracer In this series of experiments no attempt was made to find out whether the magnitude of EP continues to decay in time with or without injection of ferritin

The uptake of ferritin by the endolymphatic cells begins within a few minutes after introducing the marker into the cochlear duct. In all the specimens examined, ferritin molecules were found in the organelles of the endolymphatic cells but not free in their cytoplasm or in the intercellular spaces, basal lamina, perilymphatic cells or perilymphatic spaces (Figs. 5 7) They were found adhering to localized areas of filamentous coating of the outer surface of the cell membrane (Figs. 5 6 7 8, 10 13) or to the coating of different types of vesicular invaginations of the free surface (Figs. 5 6 7 13) and in small invaginations and small uncoated vesicular profiles of the microvilli (Fig. 8).



In the cytoplasm, ferritin was observed in different types of vesicles, tubular structures, vacuoles and multivesicular bodies. Vesicles of three types transport the ferritin inside the cytoplasm namely (*a*) coated vesicles which measured between 1 200 Å to 1 800 Å in diameter and in which the molecules were attached to the inner coating of the vesicles (Figs. 5 6 8, 9 13) (*b*) dense vesicles containing somewhat fewer ferritin molecules were characterized by a dense lumen and a diameter between 850 Å to 950 Å and usually located near multivesicular bodies (Figs. 11 12 13 14 15) and (*c*) small uncoated vesicles, measuring between 650 Å to 750 Å in diameter which showed a less dense lumen and usually contained about one to three ferritin molecules. This type of vesicle was located close to vacuoles and multivesicular bodies (Figs. 6 8 10 11 12). The tubular structures are long rods, whose diameter is usually about 950 Å. They have a dense lumen in which some of the tracer's molecules were found. These structures were sometimes continuous with coated vesicles (Figs. 9 10) or

---

Fig 13 A portion of the apical cytoplasm of an endolymphatic cell 1 hour after injection of ferritin in the endolymph. A few ferritin molecules (*arrow head*) are seen apparently attached to an area of external coating of the cell membrane. Near the luminal surface there are coated vesicles (*cv*), dense vesicles (*dv*), numerous vacuoles (*V*) and tubular structures (*t*), all containing ferritin molecules. The arrow points toward a coated vesicle which seems to be fusing with a vacuole (*V*). Notice that a large multivesicular body with abundant ferritin molecules, is surrounded by round vesicles. In t pper right side an accumulation of dense material is seen. Dense bodies (*DB* DB_2) show da k round particles and remnants of a membranous st ucture (DB_1). 79 41

Fig 14 Multivesicular body of an endolymphatic cell 2 hours afte njection of ferritin in the endolymph, showing a esicle apparently fusing with or budding from the body (*arrow*). The vesicle is surrounded by dense material. The multivesicular body contains abundant ferritin molecules and a single inner vesicle at the upper pole. No tracer is seen in the round vesicles (*rr*) surrounding the organelle while a dense vesicle (*dv*), located near its membrane contains ferritin molecules. 53 35

Fig 15 Multivesicular body of an endolymphatic cell hours after injection of ferritin in the endolymph. A comparison of the density of concentration of the tracer in this organelle w th those of *Fig. 1* (30 min) and Fig. 13 (60 min) uggest a tendency toward increase of ferritin content and decrease of the number of esicles with increase of time. There is a vesicle apparently fusi g w th or budding from the multivesicular body (*arrow*) Dense material is concentrated at one side of the body (bove the arrow). The multivesicular body is urrounded by numerous round vesicles (*rv*) w thout ferritin ud by dense vesicles (*d*) with ferritin molecules. 47 51

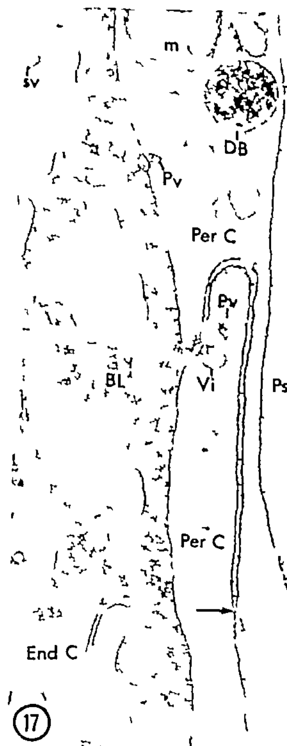
apparently fused with multivesicular bodies (Fig. 11). More frequently however they were isolated in the cytoplasm (Figs. 8 9 10 12, 13) Vacuoles of various sizes exhibited an inner coating resembling that seen in coated vesicles. Most of the ferritin molecules were embedded in the coating of the vacuole but a few could be found in the lumen (Figs. 9 10 13) The accumulation of ferritin into these vacuoles started approximately 10–20 min after injection of the tracer in the endolymph. Ferritin loaded coated vesicles (Fig. 13 arrow) were seen fused with vacuoles which apparently increased in size and contents (Fig. 13). Some of the small uncoated vesicles (Fig. 8 arrow) were either fused with or budded from, the vacuole. At 30 min multivesicular bodies were seen containing abundant ferritin molecules and numerous inner vesicles (Figs. 5 10 12) In some instances, the inner surface of the membrane of multivesicular bodies showed areas of coating material similar to that found in coated vesicles and vacuoles. The amount of ferritin molecules inside the multivesicular bodies increased progressively with time. At the one hour interval concentration of ferritin increased the multivesicular body was tranformed into a fairly round structure and the inner vesicles were accumulated in a single line along the membrane of the body (Fig. 13) After 2 hours, the concentration of ferritin was still greater the inner vesicles practically disappeared (Fig. 15) An interesting finding in multivesicular bodies was the accumulation of dense material at one pole of the body (Figs. 5 11 12, 13 14 15) This material was projected for a variable distance into the cytoplasm and frequently toward the free surface of the cell. Round and elongated vesicles dense vesicles and tubular structures always containing ferritin molecules, were embedded in this dense material at the polar area of the multivesicular body (Figs. 11 12) where numerous vesicles seemed to be fusing with, or budding from, the membrane of the body (Figs. 11 12, 14 15). Passage of ferritin molecules from one structure to another apparently occurs at this point. Outside this area and surrounding the multivesicular body were numerous small round vesicles 400 to 500 Å in diameter These vesicles contained no ferritin molecules (rv Figs. 5 11 12, 13 14 15) Similar vesicles surrounding multivesicular bodies have been described in macrophages (Cohn et al. 1966 Hirsch et al. 1968) and have been related to the Golgi complex (Novikoff et al. 1964 Brandes et al. 1964 Hirsch et al. 1968)

Perilymphatic injection

Injection of ferritin in the perilymphatic space was also associated with a slow progressive decay of EP^{+} (Fig. 4) The tracer was found in both the perilymphatic and endolymphatic cells as well as in the intercellular spaces, the basal lamina and the perilymphatic and endolymphatic spaces.



Perilymphatic cell

In all specimens studied the ferritin molecules were seen close to the cell membrane but not attached (Figs. 16 17 18 19 22). The free

An endolymphatic cell shows a vacuole (*V*) with ferr tin 61 560

urface of the perilymphatic cell, unlike that of the endolymphatic cell, exhibited no external coating. The tracer was found also in vesicular invaginations of the apical, lateral and basal plasmalemma of the perilymphatic cell (Figs. 16, 17, 19–22). In the cytoplasm, molecules of the tracer were confined to vesicles, vacuoles and dense bodies. The vesicles, varying from 500 to 1 000 Å in diameter, were located close to the apical and basal cell membranes (Figs. 16, 17, 19) but observed also in the rest of the cytoplasm (Fig. 22). The ferritin was accumulated in vacuoles (Fig. 22) and dense bodies (Fig. 17) but the concentration in the latter appeared to be the same after one or two hours since injection.

Basal lamina and intercellular spaces

In the basal lamina the ferritin molecules were accumulated in great quantity which varied directly with the time since injection. Ferritin was found in the intercellular spaces between perilymphatic cells (Fig. 17) and between endolymphatic cells (Figs. 16, 17, 18, 19–22) including the zonula adherens of their junctional complex. The tracer did not cross the zonula occludens (Figs. 16, 18).

Endolymphatic cell

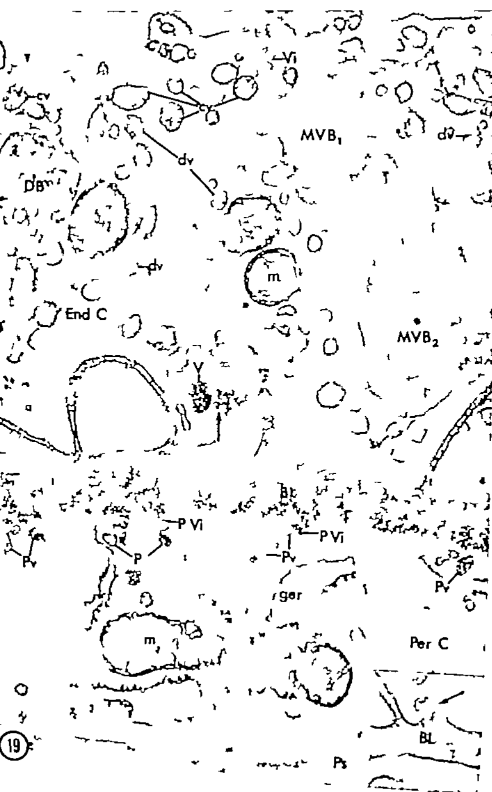
The basal plasmalemma and the lower third of the lateral cell membrane of the endolymphatic cell exhibited a few small vesicular invaginations containing numerous ferritin molecules (Figs. 19–22, arrows). No coated invaginations were seen in either the basal plasmalemma or lateral cell membrane. In the cytoplasm, molecules of the tracer were found in small vesicles, dense vesicle, coated vesicles, tubular structures, vacuoles and multivesicular bodies (Figs. 16, 18, 19–22). Comparison of perilymphatic and endolymphatic injection experiments, showed a differential distribution of ferritin. In the former, the organelles containing ferritin were distributed throughout the cytoplasm while in the latter the organelles containing ferritin were distributed only in the upper third of the cell. Tracer was also discovered in vesicular invaginations of the free surface of the endolymphatic cell (Figs. 16, 19) as well as in small vesicular invaginations of the microvilli (Figs. 20, 21). Furthermore, ferritin was seen either free in the endolymphatic space (Fig. 21) or apparently attached to the external filamentous coating of the free surface of the cell membrane (Fig. 16).

Discussion

The observations presented in this report indicate that macromolecules of ferritin were transported across Reissner's membrane from perilymph to endolymph. There was no transport of ferritin across Reissner's membrane from endolymph to perilymph, although the macromolecules were taken up by the endolymphatic cell.

Perilymphatic injection

Fig. 23 serves as a model for our assumptions regarding transport of ferritin across Reissner's membrane from perilymphatic to endolymphatic spaces. The tracer reaches the basal lamina through the intercellular space between the perilymphatic cells. The few small uncoated invaginations found in the basal, apical and lateral plasmalemma of the perilymphatic cell and the small uncoated vesicles within the cell, all containing ferritin, suggests that the tracer may also reach the basal lamina by means of a transcellular transport. A feature observed in the perilymphatic cell is the absence of areas of filamentous coating on the free surface, and the absence of



coated invaginations and coated vesicles. Perhaps the latter are related to the absence of areas of filamentous coating this may however be a fixation artifact.

Although the ferritin may be transported across the perilymphatic cell, the evidence, clearly indicates that the ferritin reaches the basal lamina predominantly by diffusion through intercellular spaces. The molecules are accumulated in the basal lamina and intercellular spaces between the endolymphatic cells up to but not within the zonula occludens. Since the zonula occludens seems to be a barrier for diffusion of ferritin, how can one explain its presence in the endolymph? Perhaps it could have resulted from a rupture of the Reissner's membrane during injection of ferritin into the perilymph. This, however is unlikely because the pressure applied to the injected fluid was negligible. Reissner's membrane can be distorted considerably before it ruptures. A more convincing argument against rupture of Reissner's membrane rests on the fact that the endocochlear potential was maintained at near normal level during and, for at least 5 min after injection of ferritin in either perilymph or endolymph A rupture of Reissner's membrane results in a mixture of perilymph and endolymph followed by a significant fall in the amplitude of the endocochlear potential (Davis et al. 1955) The observed slight decline of EP may be attributed to local damage produced by displacement of the micropipette relative to the organ of Corti that could have occurred during respiration of the animal The physiological evidence and the characteristic pattern distribution of ferritin after injection in the perilymph compared with the pattern exhibit after injection in the endolymph, to be discussed below strongly suggests that there was no contamination of endolymph with perilymph. Rather the tracer was transported across the endolymphatic cell. A question of considerable theoretical importance is how the tracer was absorbed by the endolymphatic cell transported across it and then discharged into the endolymph Although it is not valid to draw conclusions regarding dynamic relationships from electron micrographs, there are however some observations which support the processes outlined in the model (Fig. 23)

We assume that the absorption of ferritin was done by small uncoated invaginations which are consistently found along the basal plasmalemma and lower third of the lateral cell membrane. Although the tracer was diffused through the intercellular spaces up to the zonula occludens, no invaginations appeared in the upper two-thirds of the lateral plasmalemma. There was no morphological differences in the basal and lateral plasmalemma of the endolymphatic cell which may account for the specializations of invaginations mentioned above The observation that coated invaginations were never found in the basal and lateral plasmalemma suggests that the uptake of the tracer may be accomplished by small uncoated vesicles.

Regarding the transport of ferritin across the endolymphatic cell we assume a migration

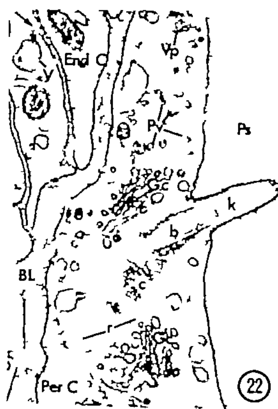
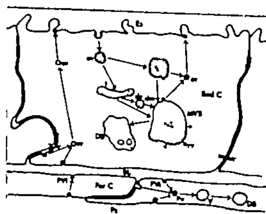
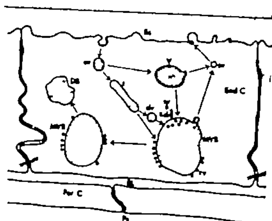
coated invaginations and coated vesicles. Perhaps the latter are related to the absence of areas of filamentous coating this may however be a fixation artifact.



Although the ferritin may be transported across the perilymphatic cell the evidence clearly indicates that the ferritin reaches the basal lamina predominantly by diffusion through intercellular spaces. The molecules are accumulated in the basal lamina and intercellular spaces between the endolymphatic cells up to but not within the zonula occludens. *Since the zonula occludens seems to be a barrier for diffusion of ferritin* how can one explain its presence in the endolymph? Perhaps it could have resulted from a rupture of the Reissner's membrane during injection of ferritin into the perilymph. This, however is unlikely because the pressure applied to the injected fluid was negligible. Reissner's membrane can be distorted considerably before it ruptures. A more convincing argument against rupture of Reissner's membrane rests on the fact that the endocochlear potential was maintained at near normal level during and, for at least 5 min after injection of ferritin in either perilymph or endolymph. A rupture of Reissner's membrane results in a mixture of perilymph and endolymph followed by a significant fall in the amplitude of the endocochlear potential (Davis et al. 1955). The observed slight decline of EP may be attributed to local damage produced by displacement of the micropipette relative to the organ of Corti that could have occurred during respiration of the animal. The physiological evidence and the characteristic pattern *distribution of* ferritin after injection in the perilymph compared with the pattern exhibit *after* injection in the endolymph to be discussed below strongly suggests that there was *no contamination* of endolymph with perilymph. Rather the tracer was transported across the endolymphatic cell. A question of considerable theoretical importance is how the tracer was absorbed by the endolymphatic cell transported across it and then discharged into the endolymph. Although it is not valid *to draw* conclusions regarding dynamic relationships from electron micrographs, there are however some observations which support the processes outlined in the model (Fig. 23).



We assume that the absorption of ferritin was done by small uncoated invaginations which are consistently found along the basal plasmalemma and lower third of the lateral cell membrane. Although the tracer was diffused through the intercellular spaces up to the zonula occludens, no invaginations appeared in the upper two-thirds of the lateral plasmalemma There was no morphological differences in the basal and lateral plasmalemma of the endolymphatic cell which may account for the specializations of invaginations mentioned above. The observation that coated invaginations were never found in the basal and lateral plasmalemma suggests that the uptake of the tracer may be accomplished by small uncoated vesicles.



Regarding the transport of ferritin across the endolymphatic cell we assume a migration

Fig. 19 Reissner's membrane two hours after injection of ferritin in the perilymph. *Perilymphatic cell.* The tracer appears in the perilymphatic space near the free surface of the cell (the luminal plasmalemma was cut tangentially). of small uncoated vesicles from base to the free surface. This assumption is reasonable because no ferritin was ever found free in the cytoplasm while small uncoated vesicles were seen throughout the cell. The distribution of these vesicles contrasts with the distribution of coated and small uncoated vesicles after injection of ferritin in the endolymph. In this case the small vesicles and other organelles containing ferritin are always located in the upper third of the cell. The transcellular transport of ferritin across the endolymphatic cell from perilymph to endolymph appears similar to that described by Bruns & Palade (1968) in the endothelial cells of the muscle capillaries. In their study the ferritin was injected in the saphenous vein The transcellular transport of the tracer by the endothelial cell was done by "plasmalemma vesicles which to a certain extent appear similar to our small uncoated vesicles. Other transcellular transport has been described in the endothelial cells of the glomerulus of the kidney by Farquhar & Palade (1962) in a number of endothelial cells, Kupffer cells and phagocytic cells in the spleen by Florey (1967) and in mesothelial cells by Odor (1956)

We assume that ferritin discharge into the endolymph is accomplished by fusion of small uncoated vesicles with the luminal plasmalemma as a reverse pinocytosis (de Duve & Wattiaux, 1966) Figures 16 and 21 show two types of invagination one coated the other uncoated. The features of these two invaginations regarding size location and coating suggest that they represent different processes. The uncoated invaginations are small, and unlike the coated ones, are consistently found at the base of the microvilli. The functional significance of their location is not apparent. On the other hand the experimental evidence from various sources (Roth & Porter 1962, Roth & Porter 1964 Fawcett 1964 Rosenbluth & Wissig 1964) indicates that the coated invaginations represent a specific process for uptake of proteins. In agreement with this concept the ferritin transported from perilymph to endolymph is again absorbed by a mechanism similar to that following injection of ferritin into the endolymph That is, the discharged ferritin is reabsorbed by coated invaginations which are found along the luminal plasmalemma. Then the small uncoated invaginations resulting, we presume, from fusion of small uncoated vesicles with the luminal plasmalemma remains as one alterna

Fig ?0 A portion of the apical cytoplasm of an endolymphatic cell two hours after injection of ferritin into the perilymph showing the tracer in numerous small vesicles (*sv*) and a dense vesicle (*dv*). The arrow points toward a small vesicle which seems to be open into the endolymphatic space however this may be debatable because the area was cut tangentially Numerous ferritin molecules are seen in the endolymphatic space near the cell membrane. 77 976

Fig 21 An area of the apical cytoplasm of an endolymphatic cell two hours after i jection of ferritin into the perilymph. The arrow points tow rd a small vesicular invagination at the base of a microvillus. Ferritin molecules a seen in the vesicular invagination, along the cell membrane and n the endolymphatic space The t ace s also found in a small esicle (*v*), a dense esicle (*d*) and in n apparent vesicular structure (*x*), with ill-defined li miting membrane. 6 586

Fig 2 Portion of Reissner's membrane hours after injection of ferriti in the perilymphatic space showing the tracer near the free surface in numerous vesicles (*Pv*), a acuole (*Vp*), basal lamina and intercellular spaces. The basal portion of the lateral plasmalemma of the endolymphatic cell shows a vesicular invagination containing ferrit n (*arro*). The tracer is also found in a vacuole (*V*). An interesting feature shown in this figure but seen only in a f w perilymphatic cells was the existence of a structure with the characteristics of a kinocilium (*k*) with a basal body (*b*), a centriole (*c*), and rootlets (*r*). The functional significance of this structure is not appar ent. Ferritin molecules are seen on the free surface of the kinocilium but not in its matrix. ?9 754

Fig 4 This model presents in diagrammatical form the events in Reissner membrane after in tion of ferritin in the endolymphatic pace Refer to the text for the discussion of these events.

ments. *The question is now how the small uncoated vesicles are formed after injection of ferritin in the endolymph.* One possibility is that they originate from small vesiculations in areas of the multivesicular body's membrane which are uncoated and perhaps from the vacuoles. The association of these organelles with small uncoated vesicles can be seen in Figs. 8, 12, 14 and 15 which also show uncoated vesicles containing ferritin in the space between luminal plasmalemma and both vacuoles and multivesicular bodies.

Recapitulating, the uptake of ferritin by the perilymphatic cell was clearly demonstrated in the micrographs but transport across the cell was not evident. On the other hand the endolymphatic cell seems to be provided with two surfaces possessing different properties regarding uptake of ferritin. The basal and lateral lower third plasmalemmas act as a specialized area for absorption of macromolecules. The membrane of these areas are deprived of coated material and the process of absorption seems to take place by means of uncoated invaginations which in turn formed uncoated vesicles transporting ferritin across the cell. The tracer was discharged into the endolymph by fusion of uncoated vesicles with luminal plasmalemma at the base of the microvilli. *The other surface of the endolymphatic cell, the luminal plasmalemma,* is able to absorb macromolecules by coated vesicles and also discharge the molecules back into the endolymph by a process of reversed pinocytosis. The molecules absorbed by the luminal plasmalemma are not transported across the cell but they were accumulated in organelles located in its upper third. Some molecules were discharged back into the endolymph by fusion of uncoated vesicles with the plasmalemma located at the base of the microvilli. The process *of discharge of the tracer into the endolymph seems to be the same whether* the molecules were absorbed by the basal or by luminal plasmalemmas. *A final* commentary regarding the results of this investigation, is that it provides a preparation which can be used for study transport of a variety of macromolecules across an epithelial membrane under physiological control.

Summary

Transport of ferritin across Reissner's membrane was studied with electron microscopy in the cat. Measurement of endocochlear potential served as control of the functional state of the cochlea. Injection of ferritin in endolymph showed uptake of ferritin molecules by coated invaginations and accumulation within numerous organelles of the endolymphatic cell. No tracer was found in the extracellular spaces, basal lamina or perilympatic cells.

After injection *of ferritin in the perilymph,* the tracer was found *in both perilymphatic* and endolymphatic cells, *intercellular* spaces and endolymph. *Ferritin* was absorbed by the basal and lateral plasmalemmas of the endo-

tive for explaining the discharge of ferritin into the endolymph.

Endolymphatic Injection

After injection of ferritin into the endolymph the uptake by the endolymphatic cell seems to follow in general, the classical stages of pinocytosis described by several authors (Bennett 1956 Bessis & Breton-Gorius, 1957 Brandt & Pappas, 1960 Bennet 1963 Choi 1963 Bowers, 1964 Fawcett, 1964 Fawcett, 1965 Holter 1965 Hirsch et al. 1968) The model representing the uptake and subsequent stages is outlined in Fig. 24 The molecules are absorbed by localized areas of filamentous coating found along the luminal plasmalemma. These areas exhibit structural features comparable to those already described in the literature (Brandt & Pappas, 1960 Bennett, *1963 Fawcett, 1964 1965 Holter 1965)* Invaginations of these specialized areas form the classical coated invaginations. Another coated structure associated with the luminal surface seen occasionally with the electron microscope was the channel-like invaginations. These long wide structures are coated along their length. There was no formation of smaller vesicles which could be associated with these channel-like invaginations. It should be noted that ferritin was always found in these structures but the fate of both ferritin and channel like invaginations was not clear in the specimens. Channel like invaginations have been described in the amoebae (Chapman Andresen & Prescott 1956 Holter 1965) and in the lung phagocytes after injection of India ink (Karrer 1960) As is well known the coated invaginations gives place to forma tion and separation of coated vesicles. The next step seems to be the formation of vacuoles by fusion of coated vesicles. The tubular structures appear also to originate from or are associated with coated vesicles as shown in Figs. 9 and 10 The question whether the tubular structures may be also formed directly from invaginations of the luminal plasmalemma remains open The electron micrographs failed to show a contribution of tubular structures to the formation of vacuoles as shown by Bowers (1964) in the pericardial cells *of an insect. The enlargement* of vacuoles by further fusion with coated vesicles forms the multivesicular bodies and perhaps tubular structures may contribute to their formation by fusion or indirectly via dense vesicles. The diameter and density of the lumen of both tubular structures and dense vesicles suggests that the latter could represent tubular structures sectioned transversally as shown in Fig 11 Apparently the multivesicular body follows several stages regarding loss of inner coating and concentration of both ferritin molecules and inner vesicles. A point of interest in our material is the presence of dense material which was repeatedly found associated with the area of fusion of tubular structures and dense vesicles with the multivesicular body As suggested by others (Novikoff & Shin 1964 Ericsson et al. 1965 Wood, 1965) the final stage of the multivesicular body could be the dense body An interesting observation in our material was the presence of small uncoated invaginations found at the base of the microvilli (see the inset of Fig. 8) These invaginations contain ferritin molecules and the question is whether the invagination represents a process for uptake or for discharge of ferritin Because the formation is uncoated and routinely found in relation with the microvilli as in the case of ferritin injected into the perilymph we tentatively interpret it as a process *for discharge of the tracer into the* endolymph. If this interpretation is correct how are the small uncoated invaginations formed when ferritin is injected into the endolymph? The presence of small uncoated vesicles containing ferritin in the neighborhood of uncoated invaginations suggests that the latter may represent a fusion of uncoated vesicles with luminal plasmalemma The process for discharging ferritin into the endolymph could be identical in the two sets of experi

ments. The question is now how the small uncoated vesicles are formed after injection of ferritin in the endolymph. One possibility is that they originate from small vesiculations in areas of the multivesicular body's membrane which are uncoated and perhaps from the vacuoles. The association of these organelles with small uncoated vesicles can be seen in Figs. 8, 12, 14 and 15 which also show uncoated vesicles containing ferritin in the space between luminal plasmalemma and both vacuoles and multivesicular bodies.

Recapitulating, the uptake of ferritin by the perilymphatic cell was clearly demonstrated in the micrographs but transport across the cell was not evident. On the other hand the endolymphatic cell seems to be provided with two surfaces possessing different properties regarding uptake of ferritin. The basal and lateral lower third plasmalemmas act as a specialized area for absorption of macromolecules. The membrane of these areas are deprived of coated material and the process of absorption seems to take place by means of uncoated invaginations which in turn formed uncoated vesicles transporting ferritin across the cell. The tracer was discharged into the endolymph by fusion of uncoated vesicles with luminal plasmalemma at the base of the microvilli. The other surface of the endolymphatic cell, the luminal plasmalemma, is able to absorb macromolecules by coated vesicles and also discharge the molecules back into the endolymph by a process of reversed pinocytosis. The molecules absorbed by the luminal plasmalemma are *not* transported across the cell but they were accumulated in organelles located in its upper third. Some molecules were discharged back into the endolymph by fusion of uncoated vesicles with the plasmalemma located at the base of the microvilli. The process of discharge of the tracer into the endolymph seems to be the same whether the molecules were absorbed by the basal or by luminal plasmalemmas. A final commentary regarding the results of this investigation, is that it provides a preparation which can be used for study transport of a variety of macromolecules across an epithelial membrane under physiological control.

Summary

Transport of ferritin across Reissner's membrane was studied with electron microscopy in the cat. Measurement of endocochlear potential served as control of the functional state of the cochlea. Injection of ferritin in endolymph showed uptake of ferritin molecules by coated invaginations and accumulation within numerous organelles of the endolymphatic cell. No tracer was *found* in the extracellular spaces, basal *lamina* or perilympatic cells.

After injection of ferritin in the perilymph, the tracer was *found* in both perilymphatic and endolymphatic cells, intercellular spaces and endolymph. Ferritin was absorbed by the basal and *lateral* plasmalemmas of the endo-

lymphatic cell and it was accumulated in various cell organelles. It was also found in coated and uncoated invaginations of the endolymphatic cell free surface. These findings indicate that transport of ferritin takes place across Reissner's membrane from perilymph toward endolymph but not in the opposite direction.

Zusammenfassung

Die Beförderung von Ferritin durch Reissnersche Membran wurde mittels Elektronenmikroskopie an Katzen untersucht. Messung des endokochlearen Potentials diente als Kontrolle für den Funktionszustand der Kochlea. Ferritininjektionen in die Endolymphe zeigte Aufnahme von Ferritinmolekülen von überzogenen Invaginationen und Ansammlung in zahlreichen Organellen der endolymphatischen Zelle. Es wurde kein Spurenmaterial in extrazellulären Zwischenräumen der Basalschicht oder perilymphatischen Zellen festgestellt.

Nach Ferritininjektionen in die Perilymphe, wurde Spurenmaterial sowohl in perilymphatischen als auch/in endolymphatischen Zellen festgestellt in Zwischenzellenraumen und in der Endolymphe. Ferritin wurde von basalen und seitlichen Plasmalemmae der endolymphatischen Zelle aufgenommen und wurde in verschiedenen Zellorganen angesammelt. Es konnte ebenfalls in überzogenen und unüberzogenen Invaginationen der freien Oberfläche der endolymphatischen Zelle festgestellt werden. Diese Resultate weisen darauf hin, dass die Beförderung von Ferritin durch Reissnersche Membran sich von der Perilymphe zur Endolymphe vollzieht nicht aber aus entgegengesetzter Richtung.

CONTENTS

Introduction

The termination within the vestibular nuclei of the first order neurons supplying the vestibular sense organs has recently been demonstrated (Gacek, 1969). The axons of the second order neurons comprising these vestibular nuclei project to [1] the nuclei of the extraocular muscle nerves, [2] the anterior horn cells of spinal cord levels, and [3] the cerebellum. These form the basis for the well-known vestibular reflexes. The first of these three reflex connections (eye responses) has attracted the most interest, both on a clinical and a laboratory level, probably because it is the most visible and accessible to precise measurement.

Accurate knowledge of the anatomical connections serving the vestibulo-ocular reflex is important for proper understanding of the physiology of this reflex in normal and abnormal states. The lack of such information was recently pointed out by Brodal (1962), (pp. 127). "Although some data are available, too little is as yet known of the detailed anatomy of the connections of the vestibular nuclei with the nuclei of the extrinsic ocular muscles to permit closer anatomico-physiological correlations." The purpose of the present study is to describe the course and precise termination of second order neurons in the vestibular nuclei which project to the III IV and VI cranial nerve nuclei. These connections were demonstrated by tracing axonal degeneration of these neurons produced by lesions in the vestibular nuclei of the cat. Descending projections were also studied but will be discussed in a general way in this report.

n the *IV and III nucleus* of the same side. This tract was thought to originate in the abducens nucleus and not the vestibular nuclei.

In 1904 van Gehuchten described the main two ascending projections from the vestibular complex. On the basis of extensive lesions in and around Deiters nucleus in the rabbit, he concluded that:

1 ascending fibers in the contralateral MLF come by way of the inferior arcuate fibers either from "the terminal nucleus" of the vestibular nerve or from the acoustic tubercle (dorsal cochlear nucleus).

2 ascending fibers in the ipsilateral MLF come by way of the superior arcuate fibers from the nucleus of Bechterew (superior vestibular nucleus).

Muskens in 1914 produced a very complete analysis of the degeneration patterns resulting from lesions throughout the vestibular system. He described three ascending tracts to the ocular nuclei:

1 A contralateral group of fibers that occupied the dorsomedial aspect of the MLF and supplied the IV and III nuclei. The origin of this system was the nucleus triangularis—the term he applied to the ventral caudal division of Deiters nucleus.

2 An ipsilateral system that traveled in the lateral part of the MLF and terminated primarily in the IV and III nuclei with a more rostral termination probable but not determinable in these studies. The superior vestibular nucleus was the sole source of this group of fibers.

3 An ipsilateral system which traveled lateral to the most lateral part of the MLF and which could be traced to midbrain levels but not beyond. He felt that the medium-sized cells in Deiters dorsal magnocellular division gave rise to this tract.

Lloyd Gray in 1926 presented a clear analysis of his results following electrolytic lesions in the vestibular nuclei of the cat. As concerns the ascending connections he described:

1 A contralateral MLF projection to the IV and III nuclei and the interstitial nucleus of Cajal and Darkschewitsch nucleus as well. He felt certain that the origin of this system was the rostral medial vestibular nucleus. This tract also terminated on the opposite abducens (VI) nucleus by way of collaterals of the axons from the medial vestibular nucleus passing into the contralateral MLF.

2 An ipsilateral MLF projection to IV III nuclei, interstitial nucleus of Cajal and Darkschewitsch nucleus. The superior vestibular nucleus was the sole source of this group of fibers.

A. T. Rasmussen (1932) in the cat described:

1 A contralateral ascending system in the MLF which projected to the levels of the IV and III nuclei. He felt the origin of this group to be either the medial or the descending vestibular nuclei since his lesions were not small enough to permit a more precise statement as to the source.

2 An ipsilateral ascending tract which occupied the lateral half of the MLF and distributed to the IV and III nuclei of the same side. He confirmed the origin of this system from the superior vestibular nucleus.

3 On the basis of his lesions he could not find any ascending projections from the lateral (Deiters) vestibular nucleus.

In 1937 Buchanan in an extensive study of lesions in the vestibular nuclei of the cat critically described the ascending and descending projections. He demonstrated three ascending projections as did Muskens:

1 A contralateral system in the MLF which arose mainly from the medial vestibular nucleus (nucleus triangularis in his terminology). A small number of fibers also was described in the ipsilateral MLF from the same source. The ultimate termination of this system to the midbrain eye nuclei were vaguely referred to but definite statement was made that the contralateral VI (abducens) nucleus received collaterals from this contralateral system. The lateral vestibular (Deiters) nucleus was also felt to contribute to this contralateral system.

Review of Literature

Many electrophysiological studies have already been reported showing the response of different eye muscles to peripheral sense organ stimulation. The reports of Bender (1964) Cohen and co-workers (1964) and Fluur (1959) are cited as examples of this type of investigation Essentially information from such studies have shown that characteristic eye movements in different planes correspond to sense organs that are stimulated by a force in the same plane Such results represent the entire three neuron arc from periphery to the effector muscle—in this case the extra-ocular muscles (Szentagothai 1950)

Precise information on connections can only be *obtained* by studying one neuron at a time. A *physiological* attempt at this is exemplified by the recent study of Tokumasu Goto & Cohen (1969) where a stimulating electrode was placed at various points of the vestibular *complex of* the monkey and produced eye movements which were somewhat different in the various regions of the nuclear complex. In their study a stimulating electrode placed in the superior vestibular nucleus produced upward rotatory eye movements, nystagmus with upward rotatory slow phases and with downward rotatory quick phases some horizontal eye movements but no downward eye movements. Stimulation of the mid portion of the vestibular complex produced upward rotatory horizontal and downward rotatory eye movements. Placement of the stimulating electrode at the junction of the rostral poles of the medial and descending vestibular nuclei produced mostly downward rotatory eye movements and nystagmus with downward rotatory slow phases and upward rotatory quick phases. An indication of the need for precise anatomical data of the second order neurons was given by their statement that "nothing is known about projections from this area" when referring to the junction of the rostral poles of the medial and descending vestibular nuclei.

Anatomical demonstration of these projections can be accomplished by the method of (*a*) axonal degeneration following lesions at the cells *of origin* or (*b*) retrograde cell changes produced by transection of the main axons of these cells. Of the two methods, the axonal degeneration technique is preferable because

(*a*) axons will regularly degenerate following injury to its cell body or axon while with the retrograde method the reaction in the cell body following a peripheral injury to its axon is not always predictable and is more difficult to assess accurately

(*b*) precise termination on cell groups within the extraocular nuclei can only be studied by staining the fiber terminals.

The most recognized comprehensive early anatomical studies of the vestibulo-ocular projections were those of Fraser (1901) Gehuchten (1904) Muskens (1914) Gray (1926) Rasmussen (1932) and Buchanan (1937)

On the basis of degeneration patterns following fairly extensive lesions in the medial longitudinal bundle and Deiter s nucleus in monkeys and cats, Fraser (1901) described two ascending projections to the midbrain

1 A contralateral system which coursed in the dorso-medial aspect of the MLF and terminated in the IV and III nuclei and the nucleus of Darkschewitsch of that side The origin of this group of fibers, he concluded, was Deiters nucleus.

2. An ipsilateral system which traveled in the lateral wing of the MLF and terminated

in the IV and III nucleus of the same side. This tract was thought to originate in the abducens *nucleus and not* the vestibular nuclei.

In 1904 van Gehuchten described the main two ascending projections from the vestibular complex. On the basis of extensive lesions in and around Deiters nucleus in the rabbit, he concluded that.

1 ascending fibers in the contralateral MLF come by way of the inferior arcuate fibers either *from "the terminal nucleus"* of the vestibular nerve or from the acoustic tubercle (dorsal cochlear nucleus).

2 *ascending* fibers in the ipsilateral MLF come by way of the superior arcuate fibers *from the nucleus* of Bechterew (superior *vestibular nucleus*).

Muskens in 1914 produced a very *complete* analysis of the degeneration patterns resulting from lesions throughout *the vestibular system.* He described three ascending tracts to the ocular nuclei:

1 A contralateral group of fibers that occupied the dorsomedial aspect of the MLF and supplied the IV and III nuclei. The origin of this system was the nucleus triangularis—the term he applied to the ventral caudal division of Deiters nucleus.

2 An ipsilateral system that traveled in the lateral part of the MLF and terminated primarily in the IV and III nuclei with a more rostral termination probable but not determinable in these studies. The superior vestibular nucleus was the sole source of this group of fibers.

3 An ipsilateral system which traveled lateral to the most lateral *part of the* MLF and which could be traced to midbrain levels *but not beyond. He felt that* the medium-sized cells in Deiters dorsal magnocellular division ga e rise *to this tract.*

Lloyd Gray in 1926 presented a clear analysis *of his results following* electrolytic lesions in the vestibular nuclei of the cat. As concerns *the* ascending connections he described.

1 A contralateral MLF projection to the IV and III nuclei and the interstitial nucleus of Cajal and Darkschewitsch nucleus as well. He felt certain that the origin of this system was the rostral medial vestibular nucleus. This tract also terminated on the opposite abducens (VI) nucleus by way of collaterals of *the axons from the* medial vestibular nucleus passing into the contralateral MLF

2 An *ipsilateral MLF projection* to IV III nuclei, interstitial nucleus of Cajal and Darkschewitsch nucleus. The superior vestibular nucleus was the sole source of this group of fibers.

A. T Rasmussen (1932) in the cat described.

1 A contralateral ascending system in the MLF which projected to the levels of the IV and III nuclei. He felt the origin of this group to be either the medial or the descending vestibular nuclei since his lesions were not small enough to permit a more precise statement as to the source.

2 An ipsilateral ascending tract which occupied the lateral half of the MLF and distributed to the IV and III nuclei of the same side. He confirmed the origin of this system from the superior vestibular nucleus.

3 On the basis of his lesions he could not find any ascending projections from the lateral (Deiters) vestibular nucleus.

In 1937 Buchanan in an extensive study of lesions in the vestibular *nuclei of the cat critically* described the ascending and descending *projections. He demonstrated three ascending* projections as did Muskens.

1 A contralateral system in the MLF which arose mainly from the medial vestibular nucleus (nucleus triangularis in his terminology). A small number of fibers also was described in the ipsilateral MLF from the same source The ultimate termination of this system to the midbrain eye nuclei were vaguely referred to but definite statement was *made* that the contralateral VI (abducens) nucleus received collaterals *from this contralateral* system. The lateral vestibular (Deiters) nucleus was also *felt to contribute* to this contralateral system.

Review of Literature

Many electrophysiological studies have already been reported showing the response of different eye muscles to peripheral sense organ stimulation. The reports of Bender (1964) Cohen and co-workers (1964) and Fluur (1959) are cited as examples of this type of investigation. Essentially information from such studies have shown that characteristic eye movements in different planes correspond to sense organs that are stimulated by a force in the same plane. Such results represent the entire three neuron arc from periphery to the effector muscle—in this case the extra-ocular muscles (Szentagothai 1950)

Precise information on connections can only be obtained by studying one neuron at a time. A physiological attempt at this is exemplified by the recent study of Tokumasu, Goto & Cohen (1969) where a stimulating electrode was placed at various points of the vestibular complex *of the monkey and produced eye* movements which were somewhat different in the various regions of the nuclear complex. In their study a stimulating electrode placed in the superior vestibular nucleus produced upward rotatory eye movements nystagmus with upward rotatory slow phases and with downward rotatory quick phases some horizontal eye movements but no downward eye movements. Stimulation of the mid portion of the vestibular complex produced upward rotatory horizontal and downward rotatory eye movements. Placement of the stimulating electrode at the junction of the rostral poles of the medial and descending vestibular nuclei produced mostly downward rotatory eye movements and nystagmus with downward rotatory slow phases and upward rotatory quick phases. An indication of the need for precise anatomical data of the second order neurons was given by their statement that "nothing is known about projections from this area when referring to the junction of the rostral poles of the medial and descending vestibular nuclei.

Anatomical demonstration of these projections can be accomplished by the method of (*a*) axonal degeneration following lesions at the cells of origin or (*b*) retrograde cell changes produced by transection of the main axons of these cells. Of the two methods, the axonal degeneration technique is preferable because

(*a*) axons will regularly degenerate following injury to its cell body or axon while with the retrograde method the reaction in the cell body following a peripheral injury to its axon is not always predictable and is more difficult to assess accurately

(*b*) precise termination on cell groups *within the extraocular nuclei can only* be studied by staining the fiber terminals.

The most recognized, comprehensive early anatomical studies of the vestibulo-ocular projections were those of Fraser (1901) Gehuchten (1904) Muskens (1914) Gray (1926) Rasmussen (1932) and Buchanan (1937)

On the basis of degeneration patterns following fairly extensive lesions in the medial longitudinal bundle and Deiter's nucleus in monkeys and cats, Fraser (1901) described two ascending projections to the midbrain

1 A contralateral system which coursed in the dorso-medial aspect of the MLF and terminated in the IV and III nuclei and the nucleus of Darkschewitsch of that side The origin of this group of fibers, he concluded was Deiters nucleus.

2 An ipsilateral system which traveled in the lateral wing of the MLF and terminated

after large lesions in the superior vestibular nucleus of the cat, that the degeneration oc curred in the medial cell group of the contralateral oculomotor (III) complex which in turn innervated the ipsilateral superior rectus muscle. He also described terminal degeneration in the ventral cell column of the ipsilateral oculomotor complex which innervated the ipsilateral medial rectus muscle. He concluded that these projections to the ipsilateral superior rectus and medial rectus from the superior vestibular nucleus corresponded to the termination of the superior and horizontal semicircular canals respectively within that nucleus, thus providing evidence of an organization to the projection of these sense organs through the superior nucleus to the eye nuclei. Also described were terminal degeneration in the trochlear and oculomotor nuclei following very large lesions in the lateral (Deiters) vestibular nucleus corresponding to otolith-ocular reflex pathways.

The second study was that of Carpenter (1966) in which he reported the degeneration patterns in the MLF and the III, IV and VI extraocular nuclei following large electrolytic lesions limited to each of the vestibular nuclei in the monkey. Essentially he found that: (1) the superior vestibular nucleus projected in an entirely ipsilateral fashion in the MLF and terminated in the ipsilateral III IV and VI nuclei. In the oculomotor complex he found all subdivisions including that supplying the inferior rectus muscle received fibers from the superior vestibular nucleus. (2) the medial vestibular nucleus projected bilaterally to the VI nucleus, and while it projected in the ascending MLF mainly in a contralateral fashion there was also a lesser ipsilateral ascending projection as well. Therefore, termination in the IVth and IIIrd nuclei was bilateral but more pronounced to the contralateral oculomotor (III) nucleus, specifically the intermediate and ventral-lateral cell groups which innervate the inferior oblique and medial rectus. In the ipsilateral oculomotor (III) complex the termination of the ipsilateral projection involved the dorsal and ventral-lateral cell columns which innervate the inferior rectus and the medial rectus respectively. These ascending systems were noted to terminate further in both of the interstitial nuclei of Cajal. (3) The lateral vestibular nucleus projected bilaterally to the abducens (VI) nuclei and to the contralateral ascending MLF similar to the projection of the medial nucleus. Ipsilateral termination in the dorsal-lateral cell column (inferior rectus) and the ventral-lateral cell group (medial rectus) of the oculomotor (III) complex was also described.

While both these studies carefully studied the terminal portions of the ascending systems, they both utilized large lesions produced electrically to the estibular nuclei and therefore could not correlate termination with origin accurately. The lack of clear uniformity and agreement on the origin and termination of the vestibulo-ocular projections remained.

The third study of vestibulo-ocular projections published very recently is that of Tarlov (1970). He has clearly shown an ipsilateral projection to the extraocular nuclei from the superior vestibular nucleus and a contralateral one from the rostral part of the medial vestibular nucleus. No mention of the ascending tract of Deiters was made in this study. He also inflicted lesions in the vestibular nuclei with the electrolytic method but carefully evaluated the size and location of these lesions and could accurately determine the origin of the two MLF systems. He was *not* able to demonstrate a correlation *of different regions of the* superior or medial vestibular *nuclei* to individual extraocular muscle.

In the *present study small* discrete lesions in the vestibular *nuclei of the* cat were produced with a one millimeter diameter probe *without the* use of electric current. After a short survival time of 6 to 7 days to allow for Wallerian degeneration, the animals were sacrificed and the Nauta silver method used to study the degeneration patterns in the brainstem and midbrain. *Origin* and termination *of* three vestibulo-ocular systems were clarified in this manner

2. An ipsilateral system in the MLF to midbrain levels which projected from the superior vestibular nucleus.

3 An ipsilateral tract lateral to the MLF which projected to midbrain levels and arose from the rostral two-thirds of Deiters (lateral vestibular) nucleus. Again termination was not precisely described to the midbrain eye nuclei but the VI (abducens) nuclei of both sides received fibers from Deiters nucleus.

A definite statement was also made by Buchanan that no ascending projections could be attributed to the descending vestibular nucleus.

In summarizing these classical anatomical studies one might say that the vestibular complex of one side is connected to the extra ocular nuclei (IV and III in particular) of both sides of the midbrain by way of both medial longitudinal fasciculi and possibly a third tract (ascending tract of Deiters) which is not contained in the MLF The important data concerning these tracts that have not been determined are (*a*) their precise origin in the vestibular nuclei (with the exception of the superior vestibular nucleus which is the undisputed sole source of the ipsilateral ascending MLF system) (*b*) their precise ultimate termination within the extra-ocular nuclei and other midbrain centers.

There are several reasons why this information is lacking despite the carefully executed investigations of these anatomists. Two factors contributed to the disagreement as to the source of the contralateral tract in the MLF and the so-called "ascending tract of Deiters

(*a*) The lesions produced in this complex area where several (*medial, lateral and descending*) of the vestibular nuclei adjoin or overlap had been extensive and usually involved more than one nucleus to some extent Limitation of the size of the lesion is very difficult when the electrolytic method is used The spread of current beyond the area of visible tissue necrosis may cause neuronal degeneration that is misleading in interpretation. In all these studies except for that of Rasmussen electric current was used to produce lesions. Although Rasmussen used a specially constructed small knife the lesions produced were extensive

(*b*) nomenclature and definition of the vestibular nuclei in this caudal area of the vestibular complex has differed. This usually has involved the terms nucleus triangularis and Deiters nucleus Muskens and Fraser referred to the ventral Deiters (lateral) which contained a layer of small and medium cells as the "nucleus triangularis while to other anatomists (Rasmussen Buchanan) nucleus triangularis clearly referred to the medial vestibular nucleus. Deiters nucleus refers in a strict sense to the lateral vestibular nucleus as identified by large or medium large multipolar cell bodies. Yet to those who use the term Deiters nucleus" in a broad sense it means an area defined by arbitrary boundaries which may include the smaller cells of an adjoining or overlapping nucleus such as the medial vestibular nucleus (see Figs. 4 5)

Information on the termination of these fiber systems is deficient for a very obvious reason All of these experiments reviewed utilized the Marchi method for selectively demonstrating axonal degeneration. This method of course relied on the osmification of free fat particles in degenerating myelin. Therefore only substantially myelinated degenerating fibers are reliably demonstrated The thinly myelinated or unmyelinated terminal portions of long axons escaped observation.

The Nauta silver method which was introduced in 1954 (Nauta, 1954 1957) selectively demonstrated even the finest terminal parts of both myelinated and unmyelinated neurons. The obvious tremendous advantage over the Marchi method led to a new era in neuroanatomical investigation

Three studies on the termination in the extraocular nuclei of ascending vestibular neurons utilizing the Nauta method have appeared

The report of Szentagothai (1964) indicated

after large lesions in the *superior vestibular* nucleus of the cat, that the degeneration occurred in the medial cell group of the contralateral oculomotor (III) complex which in turn innervated the ipsilateral superior rectus muscle. He also described terminal degeneration in the ventral cell column of the ipsilateral oculomotor complex which innervated the ipsilateral medial rectus muscle. He concluded that these projections to the ipsilateral superior rectus and medial rectus from the *superior* vestibular nucleus corresponded to the termination of the superior and horizontal semicircular canals respectively within that nucleus, thus providing evidence of an organization to the projection of these sense organs through the superior nucleus to the eye nuclei. Also described were terminal degeneration in the trochlear and oculomotor nuclei following very large lesions in the lateral (Deiters) vestibular nucleus corresponding to otolith-ocular reflex pathways.

The second study was that of Carpenter (1966) in which he reported the degeneration patterns in the MLF and the III, IV and VI extraocular nuclei following large electrolytic lesions limited to each of the vestibular nuclei in the monkey. Essentially he found that (1) the superior vestibular nucleus projected in an entirely ipsilateral fashion in the MLF and terminated in the ipsilateral III, IV and VI nuclei. In the oculomotor complex he found all subdivisions including that supplying the inferior rectus muscle received fibers from the superior vestibular nucleus. (2) the medial vestibular nucleus projected bilaterally to the VI nucleus, and while it projected in the ascending MLF mainly in a contralateral fashion there was also a lesser ipsilateral ascending projection as well. Therefore, termination in the IVth and IIIrd nuclei was bilateral but more pronounced to the contralateral oculomotor (III) nucleus, specifically the intermediate and ventral-lateral cell groups which innervate the inferior oblique and medial rectus. In the ipsilateral oculomotor (III) complex the termination of the ipsilateral projection involved the dorsal and ventral-lateral cell columns which innervate the inferior rectus and the medial rectus respectively. These ascending systems were noted to terminate further in both of the interstitial nuclei of Cajal. (3) The lateral vestibular nucleus projected bilaterally to the abducens (VI) nuclei and to the contralateral ascending MLF similar to the projection of the medial nucleus. Ipsilateral termination in the dorsal-lateral cell column (inferior rectus) and the ventral-lateral cell group (medial rectus) of the oculomotor (III) complex was also described.

While both these studies carefully studied the terminal portions of the ascending systems, they both utilized large lesions produced electrically to the vestibular nuclei and therefore could not correlate termination with origin accurately. The lack of clear uniformity and agreement on the origin and termination of the vestibulo-ocular projections remained.

The third study of vestibulo-ocular projections published very recently is that of Tarlov (1970). He has clearly shown an ipsilateral projection to the extraocular nuclei from the superior vestibular nucleus and a contralateral one from the rostral part of the medial vestibular nucleus. No mention of the ascending tract of Deiters was made in this study. He also inflicted lesions in the vestibular nuclei with the electrolytic method but carefully evaluated the size and location of these lesions and could accurately determine the origin of the two MLF systems. He was not able to demonstrate a correlation of different regions of the superior or medial vestibular nuclei to individual extraocular muscle.

In the present study small discrete lesions in the vestibular nuclei of the cat were produced with a one millimeter diameter probe without the use of electric current. After a short survival time of 6 to 7 days to allow for Wallerian degeneration, the animals were sacrificed and the Nauta silver method used to study the degeneration patterns in the brainstem and midbrain. Origin and termination of three vestibulo-ocular systems were clarified in this manner.

2. An ipsilateral system in the MLF to midbrain levels which projected from the superior vestibular nucleus.

3 An ipsilateral tract lateral to the MLF which projected to midbrain levels and arose from the rostral two-thirds of Deiters (lateral vestibular) nucleus. Again termination was not precisely described to the midbrain eye nuclei but the VI (abducens) nuclei of both sides received fibers from Deiters nucleus.

A definite statement was also made by Buchanan that no ascending projections could be attributed to the descending vestibular nucleus.

In summarizing these classical anatomical studies one might say that the vestibular complex of one side is connected to the extraocular nuclei (IV and III in particular) of both sides of the midbrain by way of both medial longitudinal fasciculi and possibly a third tract (ascending tract of Deiters) which *is not contained in the MLF* The important data concerning these tracts that have not been determined are (*a*) their precise origin in the vestibular nuclei (with the exception of the superior vestibular nucleus which is the undisputed sole source of the ipsilateral ascending MLF system) (*b*) their precise ultimate termination within the extra-ocular nuclei and other midbrain centers.

There are several reasons why this information is lacking despite the carefully executed investigations of these anatomists. Two factors contributed to the disagreement as to the source of the contralateral tract in the MLF and the so-called ascending tract of Deiters

(*a*) The lesions produced in this complex area where several (medial lateral and descending) of the vestibular nuclei adjoin or overlap had been extensive and usually involved more than one nucleus to some extent Limitation of the size of the lesion is very difficult when the electrolytic method is used. The spread of current beyond the area of visible tissue necrosis may cause neuronal degeneration that is misleading in interpretation. In all these studies except for that of Rasmussen electric current was used to produce lesions. Although Rasmussen used a specially constructed small knife the lesions produced were extensive.

(*b*) nomenclature and definition of the vestibular nuclei in this caudal area of the vestibular complex has differed. This usually has involved the terms nucleus triangularis and Deiters nucleus Muskens and Fraser referred to the ventral Deiters (lateral) which contained a layer of small and medium cells as the nucleus triangularis while to other anatomists (Rasmussen Buchanan) "nucleus triangularis clearly referred to the medial vestibular nucleus. "Deiters nucleus refers in a strict sense to the lateral vestibular nucleus as identified by large or medium large multipolar cell bodies. Yet to those who use the term Deiters nucleus in a broad sense it means an area defined by arbitrary boundaries which may include the smaller cells of an adjoining or overlapping nucleus such as the medial vestibular nucleus (see Figs. 4 5)

Information on the termination of these fiber systems is deficient for a very obvious reason All of these experiments reviewed utilized the Marchi method for selectively demonstrating axonal degeneration This method of course relied on the osmification of free fat particles in *degenerating myelin*. Therefore only substantially myelinated degenerating fibers are reliably demonstrated The thinly myelinated or unmyelinated terminal portions of long axons escaped observation

The Nauta silver method which was introduced in 1954 (Nauta 1954 1957) selectively demonstrated even the finest terminal parts of both myelinated and unmyelinated neurons. The obvious tremendous advantage over the Marchi method led to a new era in neuroanatomical investigation

Three studies on the termination in the extraocular nuclei of ascending vestibular neurons utilizing the Nauta method have appeared

The report of Szentagothai (1964) indicated

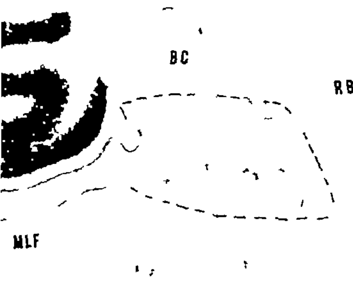

Fig. 2. Level A. Fig. 1. Transverse section through the superior vestibular nucleus (outlined area). Note proximity to brachium conjunctivum (*BC*) and restiform body (*RB*).

indicated in level C (Fig. 4) and ( ) the fact that incoming first order neurons terminate only in the ventral portion of the lateral vestibular nucleus.

Brodal (1960) in particular has demonstrated the fact that the projection to the spinal cord from this nucleus is a very highly organized one with the most rostral and ventral levels projecting to cervical levels and the dorsal and more caudal levels to the lowest portion of the cord with the intervening areas distributing in a corresponding way to other levels of the spinal cord.

Descending vestibular nucleus (DVN)

The descending or inferior vestibular nucleus is the more lateral of the two caudal vestibular nuclei, the more medial one appropriately named the medial vestibular nucleus (MVN). The descending vestibular nucleus (DVN) is most easily recognized at very caudal levels such as the photomicrograph taken at level C (Fig. 6), by the fact that its cells are interspersed among the fibers of the descending vestibular root. However the most rostral limit of the descending vestibular nucleus is somewhat more difficult to precisely delimit. The descending nucleus is immediately caudal to the ventral division of the lateral vestibular nucleus and, indeed, does undercut it in a fashion similar to the way that the lateral vestibular nucleus adjoins the superior vestibular nucleus described in the preceding section. The medial limit, however of the DVN at the most rostral pole is left mainly to individual interpretation. If one uses the dorsal acoustic stria (DAS) as the lateral boundary of the MVN at rostral levels then the smaller celled area which is just lateral to the DAS and adjacent to the ventral lateral vestibular nucleus may be included either in the DVN or in the MVN (Fig. 5.) Indeed in previous work (Gacek, 1969) on the incoming first order neurons and their sites of termination this area was referred to as belonging to the DVN. As will be pointed out later in this study it perhaps is more justifiable to include this area as part of the medial vestibular nucleus since its projection is similar to that of the medial vestibular nucleus and not at all similar to the

Preliminary to describing the experimental portion of this study a short discussion on the important anatomical considerations of the vestibular nuclei as well as of the III, IV and VI nuclei will be presented

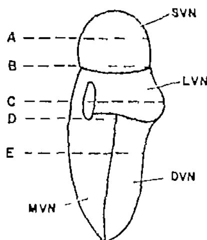

Fig 1 Outline drawing of the four major vestibular nuclei, plan view Levels *A* through *E* indicate location of Figs. through 6 which represent transverse sections through the nuclei. The clear oval area left of center marks position of the dorsal acoustic stria. *SVN* Superior vestibular nucleus *LVN* Lateral vestibular nucleus *DVN* Descending vestibular nucleus, *MVN* Medial vestibular nucleus.

VESTIBULAR NUCLEI

An outline drawing of the vestibular complex is shown in Fig. 1 Levels A through E indicate levels through the vestibular complex which will be described with accompanying photomicrographs of normal cat material stained with the thionine method for demonstrating neurons.

Superior vestibular nucleus (SVN)

The superior vestibular nucleus is the most rostral of the four main vestibular nuclei and is comprised of larger cells in the center of the nucleus and smaller cells at the periphery Fig. 2 is taken through level A and shows the cell arrangement characteristic of this nucleus. The incoming ascending branches of the first order neurons from the cristae of the semicircular canals course obliquely through the nucleus from ventrolateral to dorsomedial Axons of the cells comprising the nucleus emerge from the nucleus at the medial aspect of its rostral pole to course in a medial direction Almost all previous work on fiber pathways indicate that the cells of this nucleus project in an entirely ipsilateral fashion in the MLF to the oculomotor and trochlear nuclei

Lateral vestibular nucleus (LVN)

The lateral vestibular nucleus is immediately caudal to the superior vestibular nucleus and in fact its most rostral limit undercuts the caudal end of the superior vestibular nucleus in the manner indicated in the photomicrograph taken through level B (Fig 3) As indicated in photomicrographs taken through levels C and D (Figs. 4 5) the lateral vestibular nucleus is characterized by the giant multipolar neurons comprising this nucleus although medium and small cells populate some of the more ventral and caudal areas of the nucleus. The nucleus is bounded medially by the dorsal acoustic stria (DAS) and laterally by the restiform body and the incoming vestibular root fibers. Many investigators have felt that this nucleus can be divided into two divisions, a ventral and a dorsal one for two reasons. (1) the obvious anatomical division

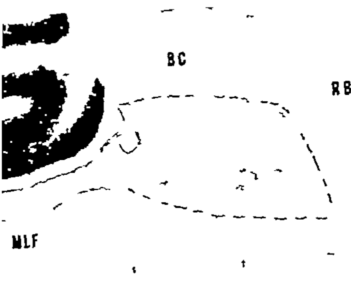

Fig. 2. Level A Fig. 1. Transverse section through the superior vestibular nucleus (outlined area). Note proximity to brachium conjunctivum (*BC*) and restiform body (*RB*).

indicated in level C (Fig. 4), and (2) the fact that incoming first order neurons terminate only in the ventral portion of the lateral vestibular nucleus.

Brodal (1960) in particular has demonstrated the fact that the projection to the spinal cord from this nucleus is a very highly organized one with the most rostral and ventral levels projecting to cervical levels and the dorsal and more caudal levels to the lowest portion of the cord with the intervening areas distributing in a corresponding way to other levels of the spinal cord.

Descending vestibular nucleus (DVN)

The descending or inferior vestibular nucleus is the more lateral of the two caudal vestibular nuclei, the more medial one appropriately named the medial vestibular nucleus (MVN). The descending vestibular nucleus (DVN) is most easily recognized at very caudal levels such as the photomicrograph taken at level E (Fig. 6) by the fact that its cells are interspersed among the fibers of the descending vestibular root. However the most rostral limit of the descending vestibular nucleus is somewhat more difficult to precisely delimit. The descending nucleus is immediately caudal to the ventral division of the lateral vestibular nucleus and, indeed, does undercut it in a fashion similar to the way that the lateral vestibular nucleus adjoins the superior vestibular nucleus described in the preceding section. The medial limit, however of the DVN at the most rostral pole is left mainly to individual interpretation. If one uses the dorsal acoustic stria (DAS) as the lateral boundary of the MVN at rostral levels then the smaller celled area which is just lateral to the DAS and adjacent to the ventral lateral vestibular nucleus may be included either in the DVN or in the MVN (Fig. 5.) Indeed in previous work (Gacek, 1969) on the incoming first order neurons and their sites of termination this area was referred to as belonging to the DVN. As will be pointed out later in this study it perhaps is more justifiable to include this area as part of the medial vestibular nucleus since its projection is similar to that of the medial vestibular nucleus and not at all similar to the

Anatomy of Vestibular and Ocular Nuclei

Preliminary to describing the experimental portion of this study a short discussion on the important anatomical considerations of the vestibular nuclei as well as of the III IV and VI nuclei will be presented

VESTIBULAR NUCLEI

An outline drawing of the vestibular complex is shown in Fig. 1 Levels A through E indicate levels through the vestibular complex which will be described with accompanying photomicrographs of normal cat material stained with the thionine method for demonstrating neurons.

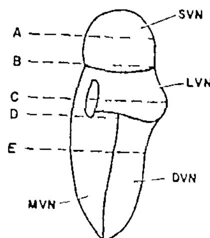

Fig 1 Outline drawing of the four major vestibular nuclei plan view Levels *A* through *E* indicate location of Figs. 2 through 6 which represent transverse sections through the nuclei. The clear oval area left of center marks position of the dorsal acoustic stria. *SVN* Superior vestibular nucleus *LVN* Lateral vestibular nucleus *DVN* Descending vestibular nucleus *MVN* Medial vestibular nucleus.

Superior vestibular nucleus (SVN)

The superior vestibular nucleus is the most rostral of the four main vestibular nuclei and is comprised of larger cells in the center of the nucleus and smaller cells at the periphery Fig. 2 is taken through level A and shows the cell arrangement characteristic of this nucleus. The incoming ascending branches of the first order neurons from the cristae of the semicircular canals course obliquely through the nucleus from ventrolateral to dorsomedial Axons of the cells comprising the nucleus emerge from the nucleus at the medial aspect of its rostral pole to course in a medial direction Almost all previous work on fiber pathways indicate that the cells of this nucleus project in an entirely ipsilateral fashion in the MLF to the oculomotor and trochlear nuclei.

Lateral vestibular nucleus (LVN)

The lateral vestibular nucleus is immediately caudal to the superior vestibular nucleus and in fact its most rostral limit undercuts the caudal end of the superior vestibular nucleus in the manner indicated in the photomicrograph taken through level B (Fig 3) As indicated in photomicrographs taken through levels C and D (Figs. 4 5) the lateral vestibular nucleus is characterized by the giant multipolar neurons comprising this nucleus although medium and small cells populate some of the more ventral and caudal areas of the nucleus. The nucleus is bounded medially by the dorsal acoustic stria (DAS) and laterally by the restiform body and the incoming vestibular root fibers. Many investigators have felt that this nucleus can be divided into two divisions, a ventral and a dorsal one for two reasons. (1) the obvious anatomical division

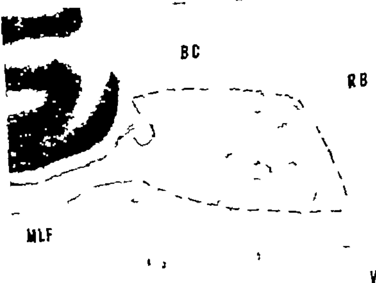

Fig. 2. Level *A* Fig. 1. Transverse section through the *superior vestibular* nucleus (outlined area). Note proximity to brachium conjunctivum (*BC*) and restiform body (*RB*).

indicated in level C (Fig. 4), and (2) the fact that incoming first order neurons terminate only in the ventral portion of the lateral vestibular nucleus.

Brodal (1960) in particular has demonstrated the fact that the projection to the spinal cord from this nucleus is a very highly organized one with the most rostral and ventral levels projecting to cervical levels and the dorsal and more caudal levels to the lowest portion of the cord with the intervening areas distributing in a corresponding way to other levels of the spinal cord.

Descending vestibular nucleus (DVN)

The descending or inferior vestibular nucleus is the more lateral of the two caudal vestibular nuclei, the more medial one appropriately named the medial vestibular nucleus (MVN). The descending vestibular nucleus (DVN) is most easily recognized at very caudal levels such as the photomicrograph taken at level E (Fig. 6), by the fact that its cells are interspersed among the fibers of the descending vestibular root. However the most rostral limit of the descending vestibular nucleus is somewhat more difficult to precisely delimit. The descending nucleus is immediately caudal to the ventral division of the lateral vestibular nucleus and, indeed, does undercut it in a fashion similar to the way that the lateral vestibular nucleus adjoins the superior vestibular nucleus described in the preceding section. The medial limit, however of the DVN at the most rostral pole is left mainly to individual interpretation. If one uses the dorsal acoustic stria (DAS) as the lateral boundary of the MVN at rostral levels then the smaller celled area which is just lateral to the DAS and adjacent to the ventral lateral vestibular nucleus may be included either in the DVN or in the MVN (Fig. 5.) Indeed in previous work (Gacek, 1969) on the incoming first order neurons and their sites of termination this area was referred to as belonging to the DVN. As will be pointed out later in this study it perhaps is more justifiable to include this area as part of the medial vestibular nucleus since its projection is similar to that of the medial vestibular nucleus and not at all similar to the

ABDUCENS (VI) NUCLEUS

The abducens or sixth cranial nerve nucleus is comprised of a group of rather large motor neurons which occupy a region immediately below the genu of the facial nerve (Fig. 4). The nucleus extends in a longitudinal direction so that it reaches from the rostral limit of the lateral vestibular nucleus to the rostral portions of the descending vestibular nucleus. The axons of these neurons project in a directly ventral direction and they innervate the ipsilateral lateral rectus muscle. It is important to remember that the dendrites of these motor neurons, as has been shown by Cajal (1909–11) and Lorente de Nó (1926), extend for considerable distances and indeed even reach into the substance of the medial vestibular nucleus. Therefore, degeneration that is described in the vicinity of the motor neuron itself is usually a conservative estimate because degeneration may be present on the dendrites of these neurons and yet be indistinguishable from degeneration within the MVN itself. The abducens is the only ocular nerve nucleus which is located in relation to the floor of the fourth ventricle.

TROCHLEAR (IV) NUCLEUS

This nucleus is comprised of fairly large motor neurons which make up a spherical nucleus that indents the dorsal surface of the MLF in a very characteristic manner (Fig. 7). This nucleus is located in the midbrain and innervates the contralateral superior oblique muscle after emerging from the dorsal surface of the midbrain. It is the smallest of the extraocular nerve nuclei both in area and in number of cells.

Fig. 7. Transverse section through the trochlear (*4*) nuclei showing the characteristic indenting of the medial longitudinal fasciculus (*MLF*).

projections of the descending nucleus. This, therefore will be included as a portion of the medial vestibular nucleus and not the descending

The outflow of the descending vestibular nucleus has been described in previous studies as projecting to cerebellar regions and in a descending direction to spinal cord by way of both the contralateral and ipsilateral MLF Several authors have indicated there is no evidence of ascending projections to the eye nuclei from the descending vestibular nucleus. (Buchanan 1937 Carpenter 1966 1960)

Medial vestibular nucleus (*MVN*)

The medial vestibular nucleus again is depicted in photomicrographs through level C through E (Figs. 4–6) It makes up the most medial half of the caudal end of the vestibular complex and is the longest nucleus of the group It parallels the length of both the lateral vestibular nucleus and the descending vestibular nucleus. Its makeup is mainly of small and medium-sized cell bodies and output is regarded as both in an ascending and a descending direction by way of the contralateral MLF

Fig. 9. Transverse section through the caudal third of the oculomotor nucleus. The medial cell columns (larger outlined area) is most prominent of the cell groups at this level, although the dorso-lateral group (smaller outlined area) can be seen also. Cf. Fig. 8. *RN* = red nucleus.

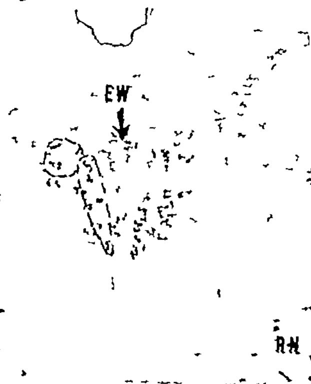

Fig. 10. Transverse section through the middle third of oculomotor complex. The medial column is smaller and the lateral cell groups are more prominent. Note the differentiation of 3 cell groups on the right-hand side of the nucleus. Cf. Fig. 8. *EW* = Edinger Westphal nucleus.

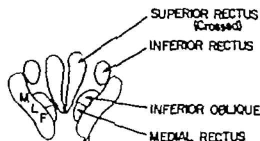

Fig. 8. Diagram of the subdivisions of the oculomotor nucleus complex. All groups except the medial column (superior rectus) innervate the ipsilateral eye muscles indicated.

OCULOMOTOR (III) NUCLEUS

The oculomotor complex is the largest and most complicated of the eye nuclei. It is located in the midbrain below the sylvian aqueduct and is immediately rostral to the IV or trochlear nucleus. The nuclear subdivisions which innervate the four extraocular muscles innervated by the III nerve have been described in the monkey by Warwick (1953) and this classification will be utilized in this study (Fig. 8). At most caudal levels through the oculomotor complex (Fig. 9) one can see primarily the medial cell column which has been shown by Warwick to innervate the contralateral superior rectus muscle. At this point the lateral cell column is not as prominent but can be seen much more clearly in the middle and rostral areas of the nuclear complex. Through the midportion of the oculomotor complex (Fig. 10) the medial cell column is less extensive while the lateral cell column is more prominent and can be seen to present into at least two subgroups—a dorsal and a ventral one. The dorsal group has been shown to innervate the inferior rectus muscle. The ventral group has been further subdivided in the monkey (Warwick) (this is not as clear in the cat) into a more dorsal group which is called the intermediate group and innervates the inferior oblique and a most ventral group which innervates the medial rectus muscle. All the cell groups in the lateral cell column innervate the ipsilateral muscle groups indicated. At the most rostral level (Fig. 11) through the oculomotor complex the medial cell column and the dorsal group of the lateral cell column are not seen and a small ventral group of the lateral cell column can be seen. This group innervates the medial rectus muscle primarily. The two other nuclei important to this study since they represent the most rostral terminus of the vestibulo-ocular projection are the nuclei associated with the MLF rostral to the oculomotor complex. These are the nucleus of Darkschewitsch (ND) and the interstitial nucleus of Cajal (IC). These are relatively condensed accumulations of small cells. The nucleus of Darkschewitsch is located dorso-lateral to the MLF and the interstitial nucleus of Cajal is more ventro-laterally located in relation to this medial longitudinal bundle. These are illustrated in Fig. 12.

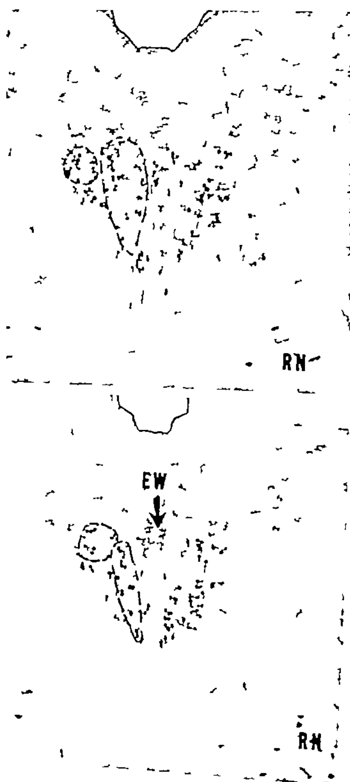

Fig. 9 Transverse section through the caudal third of the oculomotor nucleus. The medial cell columns (larger outlined area) is most prominent of the cell groups at this level, although the dorso-lateral group (smaller outlined area) can be seen also. Cf. Fig. 8. *RN* = red nucleus.

Fig. 10 Transverse section through the middle third of oculomotor complex. The medial column is smaller and the lateral cell groups are more prominent. Note the differentiation of 3 cell groups on the right-hand side of the nucleus. Cf. Fig. 8. *EW* = Edinger-Westphal nucleus.

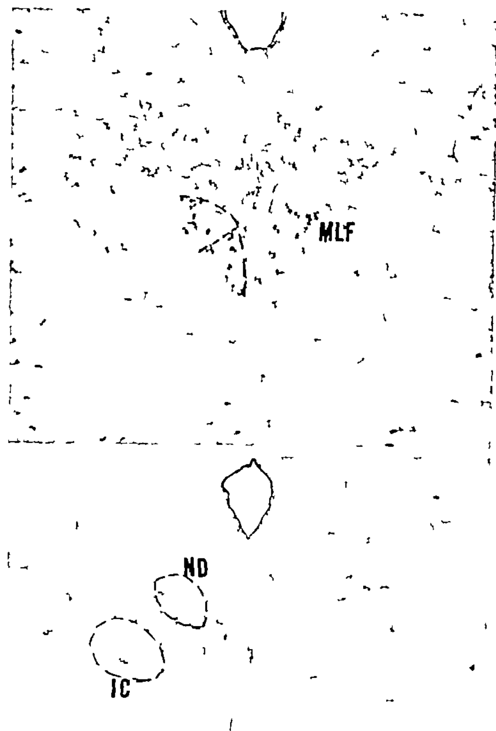

Fig. 11. Transverse section through the rostral third of the oculomotor nucleus. At this level the medial cell column and the dorsolateral group are not visible and only the intermediate-ventral lateral group (outlined) is recognizable.

Fig. 12. Transverse section rostral to the oculomotor nucleus showing the nucleus of Darkschewitsch (*ND*) and the interstitial nucleus of Cajal (*IC*).

Materials and Methods

Thirty-five healthy young adult cats were used in this study. After adequate intraperitoneal injection of Nembutal (30 mg per kg), the skull and back of the neck were shaved and prepped for surgical procedure. A midline skin incision separating the posterior neck muscles and removal of the occipital portion of the bone from the foramen magnum to the lambdoidal crest was then carried out with rongeurs in order to obtain exposure of the posterior fossa. After careful incision and reflection of dura and arachnoid, the right side of the cerebellar hemisphere and vermis were carefully elevated from the dorsal surface of the brainstem with the use of the operating microscope. Care was used to avoid interruption of the vascular supply. This elevation was carried out with a malleable metal strip retractor until the dorsal acoustic stria coursing medially from the dorsal cochlear nucleus could be seen as the principal landmark. The most medial extent of the dorsal acoustic stria served as a landmark for the vestibular nuclei. At this point if an animal was to serve as a control no further surgery was performed. If the animal was to be used as an experimental lesion animal, then a straight probe of 1 mm diameter was inserted in a rostro-ventral direction to a predetermined depth in order to produce a lesion in the intended vestibular nucleus on the right side. For lesions in the rostral part of the vestibular complex, that is the superior vestibular nucleus, the probe was inserted dorsal and rostral to the dorsal acoustic stria and passed in a rostro-ventral and slightly medial direction. If lesions were to be made in the more caudal aspects of the vestibular complex lesions, the probe entered the dorsal surface of the vestibular area, caudal and ventral to the dorsal acoustic stria in a similar direction. The probe was withdrawn and the operative defect closed by placing a piece of gelfoam over the exposed area of cerebellum and approximating the occipital and temporal muscles loosely to allow for postoperative expansion of the cerebellum. The skin closure was performed in the usual manner with interrupted sutures.

Animals were not administered antibiotics but were given 5% glucose and water the first postoperative day.

Detailed recordings of eye movements in these animals were not obtained. With the exception of one or two animals with more extensive lesions, no spontaneous gross eye movements were noted. Therefore, electronystagmographic recording of ocular movement would be necessary. Such instrumentation was not available.

In addition, short survival tissues of 6–7 days were necessary to optimally demonstrate degenerating nerve terminals in the ocular nuclei. Cerebellar edema from retraction in the posterior fossa surgical approach introduces another factor in the animal's functional deficit during the immediate postoperative period. Therefore, interpretation of recordings during this period would be most difficult.

After a survival period of 6 or 7 days the animals were perfused intravitally with ten percent formalin with three percent potassium dichromate added. The calvarium was removed and the dura reflected in order to allow further fixation by immersion in 10% formalin. This was accomplished by placing the head and brain in a jar with 500 cc of 10% neutralized formalin. After two to three

Fig. 11. Transverse section through the rostral third of the oculomotor nucleus. At this level the medial cell column and the dorsolateral group are not visible and only the intermediate-ventral lateral group (outlined) is recognizable.

Observations

A. CONTROL ANIMALS

(a) The brainstems of three cats, in which operative exposure alone of the vestibular nuclei was carried out, were carefully examined. No degeneration was found in the extraocular nuclei of all three animals. Therefore, the posterior fossa approach for producing vestibular nuclear lesions was satisfactory for this study

(b) Fig. 13 summarizes the lesion and resulting degeneration pattern in animal no. 92. The lesion was produced by inserting the probe through the dorsal division of the lateral (Deiters) vestibular nucleus rostrally along the dorsal border of the superior vestibular nucleus. Here the central portion of the brachium conjunctivum was involved and the superior vestibular nucleus spared (Fig. 14).

There was no degeneration in either MLF The degenerating fibers of the brachium conjunctivum could be followed across the midline at the level of the interpeduncular nucleus and into the contralateral Red Nucleus where heavy terminal degeneration was found. However close examination revealed many fine degenerating fibers in small groups emanating dorsally from the area of the Red Nucleus. These fibers pierced the contralateral MLF at right angles (see Fig. 15) in the area of the III and IV nuclei. Terminal degeneration was clearly found in the medial cell group of the contralateral III nucleus (Fig. 16) and in the rostral and dorsal rim of the contralateral IV nucleus (Fig. 17). This pattern and distribution of degenerating fibers from lesions in brachium conjunctivum was clearly and constantly found in all five animals in this group

This finding confirmed the presence of a direct cerebello-ocular projection in the cat. Knowledge of distribution of this projection permitted accurate evaluation of lesions in the periphery of the superior vestibular nucleus where the brachium conjunctivum was also involved.

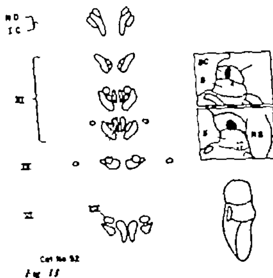

Fig. 13

B. EXPERIMENTAL ANIMALS

Although all twenty-four experimental animals with lesions in the vestibular nuclei were reconstructed, ten such reconstructions will be described in detail since they show the significant ascending projections to the extraocular nuclei.

The lesions and degeneration patterns are graphically illustrated in a summary diagram for each animal described in the text. The lesion is located by a solid black area in its rostro-caudal extent on the drawing in the lower right corner and in its dorsoventral location on outlines of selected sections through

days of fixation by immersion the brainstems were removed under the operating microscope to avoid trauma or traction on the cranial nerves emerging from the brainstem and mid brain areas. This part of the brain was further fixed by immersion in ten percent formalin for 48 hours before portions of the brainstem and midbrain were blocked and readied for sectioning. Frozen sections were cut at 30 μ and were then processed with the Nauta technique of silver staining.

Sections of each animal were examined carefully and reconstructed to depict the lesion and degeneration patterns emanating from the lesion in each animal.

Of the total of thirty-five animals, three animals died in the postoperative period for unknown reasons and twenty-four were utilized as experimental animals with lesions in the vestibular nuclei. The other eight cats served as the control group

Two significant points were studied in the control group

1 It was considered possible that degeneration in the extraocular nuclei could be produced by traction or pressure on the brainstem nuclei or cerebellum during the operative procedure. Three cats were operated upon in the manner previously described to expose the vestibular nuclear area but no intentional lesion made with the probe. After the usual 6–7 day survival period, the brainstems and ocular nuclei were examined in these animals.

2. Direct cerebello-ocular fiber projections through the brachium conjunctivum have been described in several animal species (Allen 1924 Carpenter 1964 Van Gehuchten 1905 Gerebtzoff 1936 1941 Klimoff 1896 1899 Rasmussen 1932)

Since the brachium conjunctivum is immediately adjacent to the superior vestibular nucleus and is frequently involved in lesions of this nucleus, the presence and termination of this projection was studied in five cats. These cats represented those in which the probe had missed its intended target in the superior vestibular nucleus and involved different portions of the brachium conjunctivum superior to the nucleus.

Observations

A. CONTROL ANIMALS

(a) *The brainstems of three cats, in which operative exposure alone of the vestibular nuclei was carried out, were carefully examined.* No degeneration was found in the extraocular nuclei of all three animals. Therefore, the posterior fossa approach for producing vestibular nuclear lesions was satisfactory for this study

(b) Fig. 13 summarizes the lesion and resulting degeneration pattern in animal no. 92. The lesion was produced by inserting the probe through the dorsal division of the lateral (Deiters) vestibular nucleus rostrally along the dorsal border of the superior vestibular nucleus. Here the central portion of the brachium conjunctivum was involved and the superior vestibular nucleus spared (Fig. 14).

There was no degeneration in either MLF The degenerating fibers of the brachium conjunctivum could be followed across the midline at the level of the interpeduncular nucleus and into the contralateral Red Nucleus where heavy terminal degeneration was found. However close examination revealed many fine degenerating fibers in small groups emanating dorsally from the area of the Red Nucleus. These fibers pierced the contralateral MLF at right angles (see Fig. 15) in the area of the III and IV nuclei. Terminal degeneration was clearly found in the medial cell group of the contralateral *III nucleus* (Fig. 16) and in the rostral and dorsal rim of the contralateral IV nucleus (Fig. 17). This pattern and distribution of degenerating fibers from lesions in brachium conjunctivum was clearly and constantly found in all five animals in this group.

This finding confirmed the presence of a direct cerebello-ocular projection in the cat. Knowledge of distribution of this projection permitted accurate evaluation of lesions in the periphery of the superior vestibular nucleus where the brachium conjunctivum was also involved.

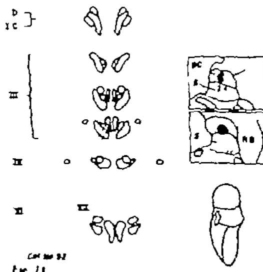

Fig. 13

B EXPERIMENTAL ANIMALS

Although all twenty-four experimental animals with lesions in the vestibular nuclei were reconstructed, ten such reconstructions will be described in detail since they show the significant ascending projections to the extraocular nuclei.

The lesions and degeneration *patterns* are graphically illustrated *in a summary diagram* for each *animal* described in the text. The lesion is located by a solid black area in its rostro-caudal extent on the drawing in the lower right corner and in its dorsoventral location on outlines of selected sections through

the vestibular nuclei at the right upper and middle portions of the diagram. Degenerating fibers are represented by dashed lines emanating from the lesion area in the outline of the vestibular complex at lower right. The six drawings in the center column represent the cross-section outlines of the MLF and the extraocular nuclei and midbrain nuclei as identified by the labels at left. Degenerating fibers coursing in the MLF are shown as heavy dots and terminal degeneration within the nuclei as a fine stippled area

I *Lesions in the superior vestibular nucleus* Lesions produced in the superior vestibular nucleus were made by passing the probe in a ventro-medial direction after inserting the probe above the dorsal acoustic stria. This lesion necessarily involved the dorsal division of the lateral vestibular nucleus in all cases (Figs. 18 25 31 36) However as determined in this study and those of others (Buchanan 1937 Carpenter 1966) lesions in this portion of the lateral vestibular nucleus did not contribute to any ascending degeneration in the brainstem Degeneration from lesions in this portion of the lateral nucleus was entirely in a descending direction by way of the ipsilateral vestibulo-spinal tract. Therefore all ascending degeneration produced in this manner could be correlated with the area of superior vestibular nucleus involved.

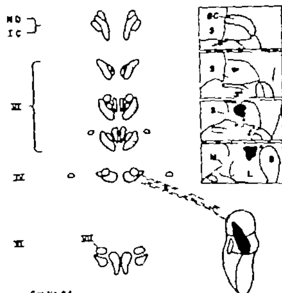

Fig 18.

Cat no. 84 (see Fig 18)

In this animal the lesion involved the most caudal and medial portion of the superior vestibular nucleus (Fig. 19). Since the axons of the cells in the intact rostral portion of the nucleus (Fig. 20) leave the rostral pole of the nucleus, the degeneration pattern in this animal correlated with the caudal-medial part of the SVN

Degenerating nerve fibers of all sizes were followed in a rostro-medial direction from the SVN and entered the lateral wing of the ipsilateral MLF at the rostral level of the fourth ventricle. These degenerating fibers retained a lateral position in the MLF throughout the midbrain. Collaterals were observed as these fibers passed the IV and III nuclei. Terminal degeneration was significant in the ipsilateral IV nucleus (Fig. 21). In the III nuclear complex terminal degeneration was heaviest in the ipsilateral intermediate-lateral group although a lesser amount of degeneration also was found in the ipsilateral ventral cell mass. (Fig. 22 *A B*) There were also degenerating fibers crossing the midline (Fig. 23) within the oculomotor complex to terminate in the inter mediate and ventral lateral cell column of the contralateral side to a lesser degree. The medial cell group and the dorsal-lateral cell group of both sides of the oculomotor com-

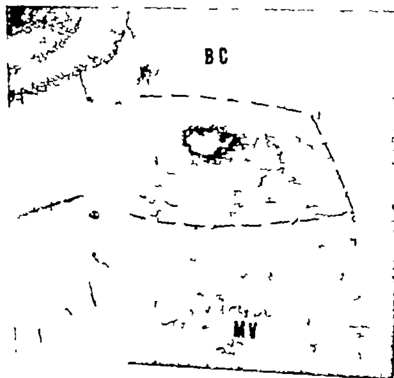

Fig 19 Transverse section through the caudal half of the superior vestibular nucleus showing the lesion in the medial portion of the nucleus. Cat, 84. *MV* = motor nucleus of trigeminal nerve.

the vestibular nuclei at the right upper and middle portions of the diagram. Degenerating fibers are represented by dashed lines emanating from the lesion area in the outline of the vestibular complex at lower right. The six drawings in the center column represent the cross-section outlines of the MLF and the extraocular nuclei and midbrain nuclei as identified by the labels at left. Degenerating fibers coursing in the MLF are shown as heavy dots and terminal degeneration within the nuclei as a fine stippled area.

I. *Lesions in the superior vestibular nucleus*
Lesions produced in the superior vestibular nucleus were made by passing the probe in a ventro-medial direction after inserting the probe above the dorsal acoustic stria. This lesion necessarily involved the dorsal division of the lateral vestibular nucleus in all cases (Figs. 18, 25, 31, 36). However as determined in this study and those of others (Buchanan 1937, Carpenter 1966) lesions in this portion of the lateral vestibular nucleus did not contribute to any ascending degeneration in the brainstem. Degeneration from lesions in this portion of the lateral nucleus was entirely in a descending direction by way of the ipsilateral vestibulo-spinal tract. Therefore all ascending degeneration produced in this manner could be correlated with the area of superior vestibular nucleus involved.

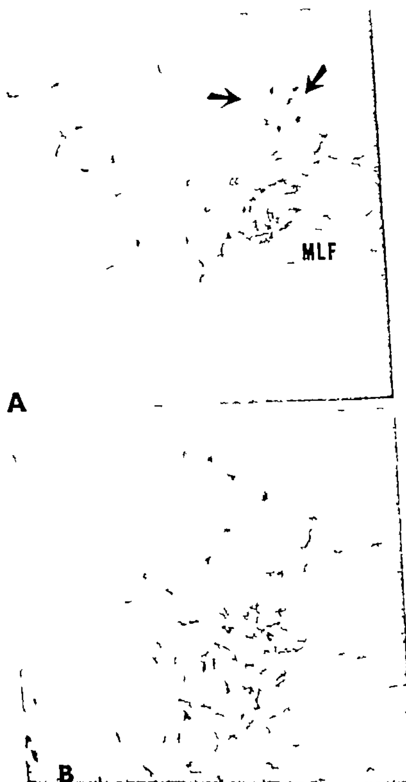

Fig 22 (A) Medium power view through the oculomotor nucleus of Cat 84. Degenerating fibers are shown coursing from the lateral part of the MLF and terminating in the ventral lateral part of the nucleus but not in the dorso-lateral group (*arrows*). Less prominent degeneration in the contralateral nucleus is not visible at this power (B) This high power view of the ipsilateral oculomotor nucleus shown in (A) more clearly shows the localization of degeneration in the ventro-lateral subdivision and not in the dorso-lateral group.

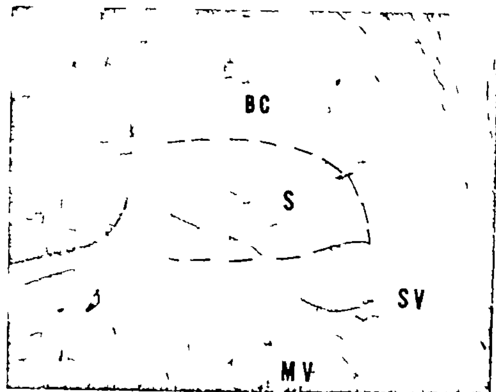

Fig. 0 Section through the rostral half of the superior vestibular nuclei (*S*) of Cat 84 demonstrate no involvement by the lesion. *MV* = motor nucleus of trigeminal nerve. *SV* sensory nucleus of trigeminal nerve.

Fig. 1 High power view through the ipsilateral MLF and trochlear (*4*) nucleus of Cat 84. Degenerated fibers (between arrows) occupy the lateral half of the MLF and there is terminal degeneration in the trochlear nucleus.

plex were strikingly free of any degeneration (Figs. 2? 23).

The degenerating fibers in the ipsilateral MLF could be finally followed to the level of the nucleus of Darkschewitsch and the interstitial nucleus of Cajal where definite preterminal degeneration was found in both nuclei of the ipsilateral side (Fig. 24). No more rostral continuation of degenerating fibers was seen. No degeneration was found in the main nuclear mass of the abducens (VI) nerve nor were any descending fibers seen in the MLF.

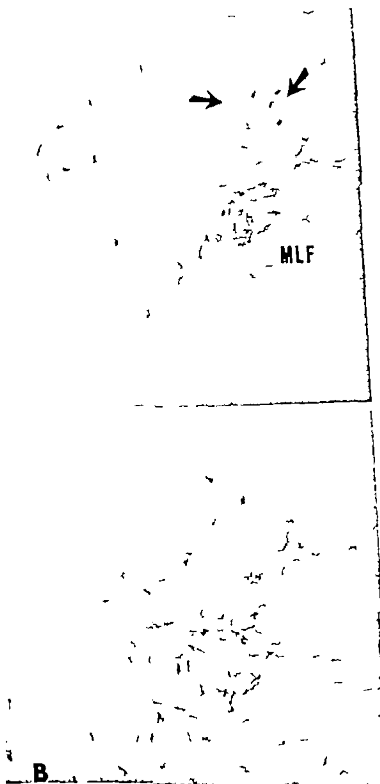

Fig. 22. (A) Medium power view through the oculomotor nucleus of Cat 84. Degenerating fibers are shown coursing from the lateral part of the MLF and terminating in the *ventral lateral part of the* nucleus but not in the dorso-lateral group (*arrows*). Less prominent degeneration in the contralateral nucleus is not visible at this power. (B) This high power view of the ipsilateral oculomotor nucleus shown in (A) more clearly shows the localization of degeneration in the ventrolateral subdivision and not in the dorso-lateral group.

Fig. 23. High power view of the oculomotor complex in Cat 84 showing a degenerated fiber (*arrow*) crossing the midline within nucleus to contralateral side.

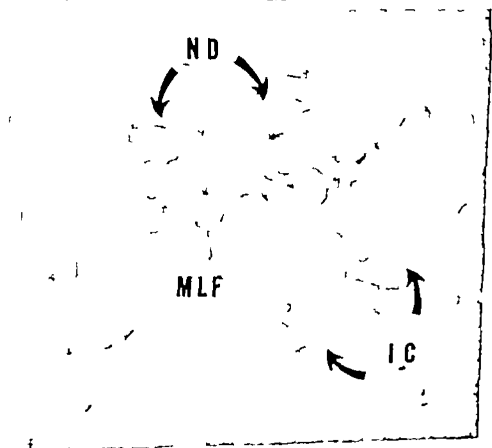

Fig. 24. High power view of terminal degeneration (*arrows*) in the ipsilateral nucleus of Darkschewitsch (*ND*) and interstitial nucleus of Cajal (*IC*) of Cat 84.

Cat no. 94 (see Fig 25)

The lesion essentially followed the same path as in Animal 84 but extended to the rostral pole of the superior vestibular nucleus. In addition to damaging some of the same cells in the nucleus as in the previous animal, this narrow lesion also involved cells in the dorsal portion of the rostral half of the SVN (Fig. 26).

Again degenerating axons were seen emanating from the rostro-medial pole of the SVN (Fig. 27), and entered the ispilateral MLF where they occupied the lateral half of the bundle throughout its ascending course (Figs. 28 and 29).

Terminal degeneration was found in the ipsilateral IV nucleus (Fig. 28 *A* *B*) and in the III complex, the bilateral degeneration pattern was similar to Animal 84, with the ipsilateral side having the more significant amount Notable differences from the previous animal, however were: (1) a small but definite amount of degeneration in the ipsilateral medial cell column, and (2) heavier degeneration in the ventral portion of the lateral cell column in the III complex. These differences would indicate that the rostral part of SVN have projections to the muscles innervated by these cell groups namely the

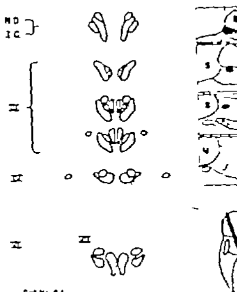

Fig. 25

superior rectus and the medial rectu dorsal lateral cell group in the ocul complex was again strikingly free of a generating fibers (Fig. 30).

The rostral terminal degeneration o degenerating fibers in the MLF aga found in the nucleus of Darkschewits the interstitial nucleus of Cajal.

No degeneration was found in the ab (VI) nucleus of either side.

Fig. [illegible]*3* High power view of the oculomotor complex in Cat 84 showing a degenerated fiber (*arrow*) crossing the midline within nucleus to contralateral side

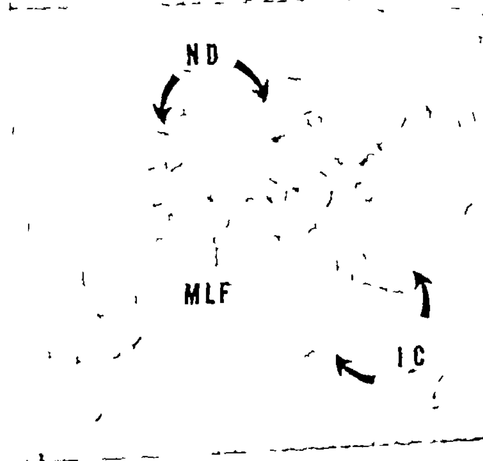

Fig. [illegible]*4* High power view of terminal degeneration (*arrows*) in the ipsilateral nucleus of Darkschewitsch (*ND*) and interstitial nucleus of Cajal (*IC*) of Cat 84

Fig. 28 (*A*) Ipsilateral MLF and trochlear nucleus of Cat 94 showing degenerated axons in lateral half of MLF (arrow) and terminal degeneration in the nucleus. (*B*) Contralateral MLF and trochlear nucleus in Cat 94 showing complete absence of degeneration.

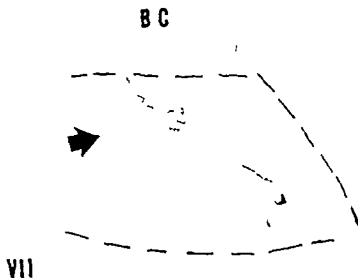

Fig. 26. Arrow points to the lesion in midportion of superior vestibular nucleus (outlined area) of Cat 94.

Fig. 27. High power view of the rostral end of lesion in the superior nucleus of Cat 94. Arrow points to degenerated fiber which will enter the MLF. The brachium conjunctivum (BC) escaped injury.

Cat no. 91 (see Fig 31)

The lesion again involved the dorsal LVN caudal to the SVN. In the SVN the lesion extended from the center of the caudal part of the nucleus to the ventral side of the rostral end of the nucleus. The lesion even extended beyond this into the *brachium conjunctivum*. A large number of degenerating fibers coursing medially in the rostral portion of the *SVN* (Fig. 32) entered the lateral wing of the ipsilateral MLF and retained this characteristic position through the midbrain (Figs. 33, 34).

The terminal degeneration pattern in IV (Fig. 33 *A*) and III was identical to that of Animal 94 except that the amount in the ipsilateral medial cell column of III was heavier (Fig. 35). Terminal degeneration ipsilaterally in the rostral nuclei of Darkschewitsch and Cajal was again seen and no degeneration was found in the VI nucleus.

The heavy terminal degeneration in the *contralateral medial cell group of* III (Fig. 35) and the dorsal part of contralateral IV (Fig. 33 *B*) were associated with the injury to the ipsilateral brachium conjunctivum and not with the SVN lesion.

The lesion in this animal confirmed the findings in Animal 94 that the rostral part of the SVN projected to the ipsilateral medial column and the ventral lateral column of III because this lesion, which interrupted more neurons in the rostral SVN than in Cat 94 was correlated with a heavier degeneration pattern in these two cell divisions of III. The importance of careful reconstruction of the lesion and of the degeneration from control lesions of the brachium conjunctivum was emphasized in this and the following animal.

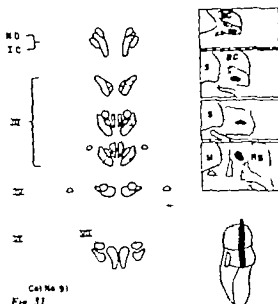

Fig 31

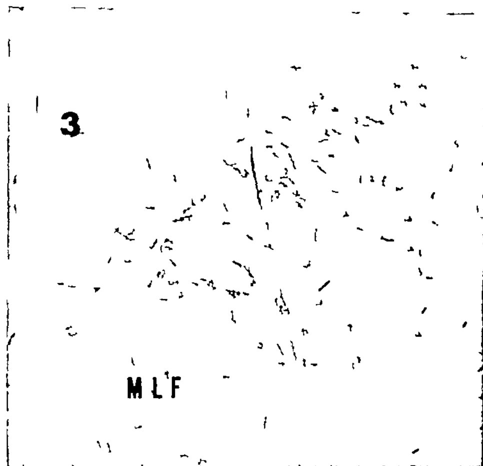

Fig. 29. High power view of the ipsilateral MLF and oculomotor nucleus *(3)* in Cat 94. Degenerated fibers remain located in the lateral part of the MLF and send terminating collaterals to the ventrolateral groups in the oculomotor nucleus.

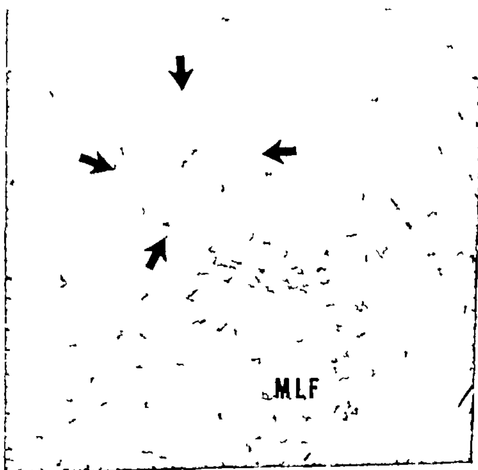

Fig. 30. Ipsilateral oculomotor nucleu of Cat 94 showing absence of degeneration in the dorso-lateral cell group (ar o) while more ventral area are covered with degenerating fibers.

Cat no. 91 (see Fig. 31)

The lesion again involved the dorsal LVN caudal to the SVN. In the SVN the lesion extended from the center of the caudal part of the nucleus to the ventral side of the rostral end of the nucleus. The lesion even extended beyond this into the brachium conjunctivum. A large number of degenerating fibers coursing medially in the rostral portion of the SVN (Fig. 32) entered the lateral wing of the ipsilateral MLF and retained this characteristic position through the midbrain (Figs. 33–34).

The terminal degeneration pattern in IV (Fig. 33 A) and III was identical to that of Animal 94 except that the amount in the ipsilateral medial cell column of III was heavier (Fig. 35). Terminal degeneration ipsilaterally in the rostral nuclei of Darkschewitsch and Cajal was again seen and no degeneration was found in the VI nucleus.

The heavy terminal degeneration in the contralateral medial cell group of III (Fig. 35) and the dorsal part of contralateral IV (fig. 33 B) were associated with the injury to the ipsilateral brachium conjunctivum and not with the SVN lesion.

The lesion in this animal confirmed the findings in Animal 94 that the rostral part of the SVN projected to the ipsilateral medial column and the ventral lateral column of III because this lesion, which interrupted more neurons in the rostral SVN than in Cat 94 was correlated with a heavier degeneration pattern in these two cell divisions of III. The importance of careful reconstruction of the lesion and of the degeneration from control lesions of the brachium conjunctivum was emphasized in this and the following animal.

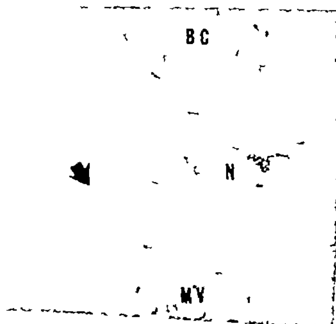

Fig. 3–. High power view of the rostral end of the lesion (N) in superior vestibular nucleus of Cat 91. Arrow points to degenerated axons leaving the nucleus for the MLF. MV = motor nucleus of trigeminal.

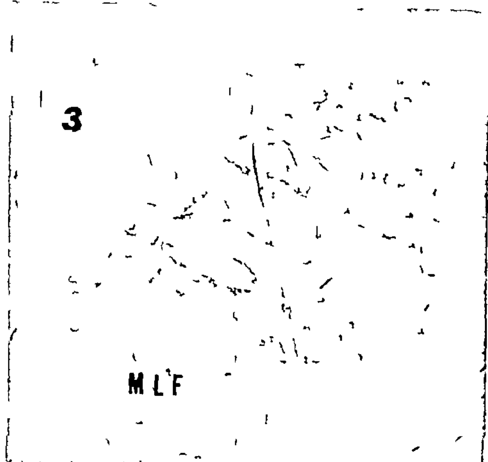

Fig 29 High power view of the ipsilateral MLF and oculomotor nucleus (*3*) in Cat 94. Degenerated fibers remain located in the lateral part of the MLF and send *terminating collaterals to the ventrolateral groups* in the oculomotor nucleus.

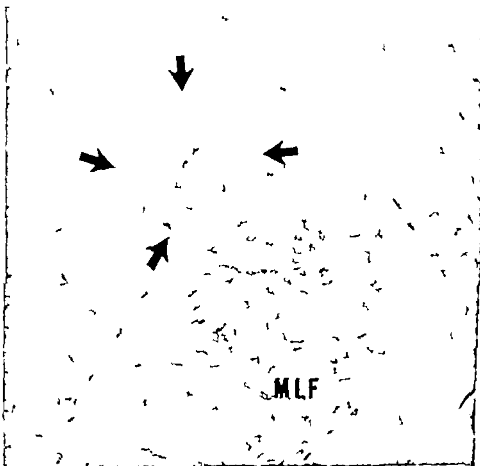

Fig 30 Ipsilateral oculomotor nucleus of Cat 94 showing absence of degeneration in the dorso-lateral cell group (*arrows*) while more ventral areas are covered with degenerating fibers.

Cat no. 91 (see Fig 31)

The lesion again involved the dorsal LVN caudal to the SVN In the SVN the lesion extended from the center of the caudal part of the nucleus to the ventral side of the rostral end of the nucleus. The lesion even extended beyond this into the brachium conjunctivum. A large number of degenerating fibers coursing medially in the rostral portion of the SVN (Fig. 32) entered the lateral wing of the ipsilateral MLF and retained this characteristic position through the midbrain (Figs. 33 34).

The terminal degeneration pattern in IV (Fig. 33 *A*) and III was identical to that of Animal 94 except that the amount in the ipsilateral medial cell column of III was heavier (Fig 35). Terminal degeneration ipsilaterally in the rostral nuclei of Darkschewitsch and Cajal was again seen and no degeneration was found in the VI nucleus.

The heavy terminal degeneration in the contralateral medial cell group of III (Fig. 35) and the dorsal part of contralateral IV (Fig 33 *B*) were associated with the injury to the ipsilateral brachium conjunctivum and not with the SVN lesion.

The lesion in this animal confirmed the findings in Animal 94 that the rostral part of the SVN projected to the ipsilateral medial column and the ventral lateral column of III because this lesion, which interrupted more neurons in the rostral SVN than in Cat 94, was correlated with a heavier degeneration pattern in these two cell divisions of III. The importance of careful reconstruction of the lesion and of the degeneration from control lesions of the brachium conjunctivum was emphasized in this and the following animal.

Cat no. 66 (see Fig 36)

This very small lesion involved the dorsal LVN but was located in the lateral portion of the SVN throughout most of its extent (Fig 37) The rostral pole of the SVN was spared as the lesion was more dorsally positioned and eventually extended into the brachium conjunctivum.

A very few degenerating fibers were followed up the MLF to the IV (Fig 38) and III nuclei and the two rostral nuclei of the ipsilateral side Noteworthy was the absence of degeneration in the ipsilateral medial cell column of III (Fig. 39) this again correlated with the intact rostral portion of the SVN

The most striking degeneration pattern was that associated with the lesion in the brachium conjunctivum and involved the dorsal part of the contralateral IV nucleus (Fig 38 *B*) and the medial cell column of contralateral III (Fig. 39 *A*)

The most important point to be derived from this lesion was that it suggests that the smaller cells that make up the lateral portion of SVN probably do not contribute to the ascending ocular projection This lesion should have injured a significant number of these cells by its location. The very small number of ipsilateral degenerating fibers probably belong to a few of the larger cells which may be found interspersed with these small ones in the periphery of the SVN

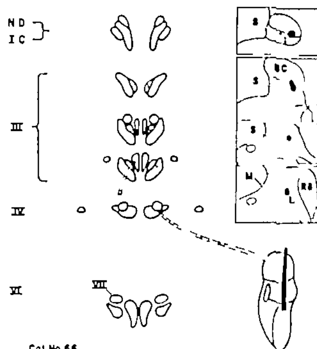

Fig 36

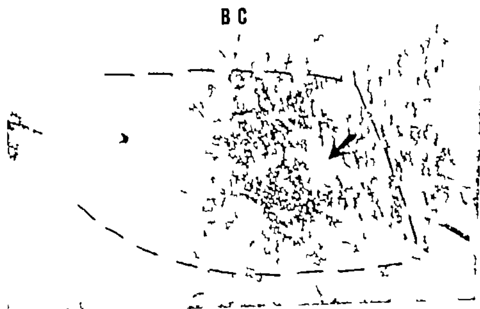

Fig 37 Transverse section through the superior vestibular nucleus (outlined area) of Cat 66. Arrow points to the small diameter lesion in the lateral portion of the nucleus.

Summary of lesions in SVN

Lesions and degeneration patterns indicated that the superior vestibular nucleus projected only into the ipsilateral MLF where its fibers are located in the lateral half. These fibers terminated in the IV and III nuclei in the following manner: ipsilateral IV, bilateral intermediate and ventral lateral cell groups of III with ipsilateral side more marked, ipsilateral medial cell group of III.

Neurons in the caudal-medial part of the SVN project primarily to IV (contralateral superior oblique) and the intermediate lateral cell group of III (ipsilateral inferior oblique). Those in the rostral and central part of SVN project mainly to IV and to the medial cell column (contralateral superior rectus) and ventral-lateral group (ipsilateral medial rectus) of III.

The SVN does not project to the VI nucleus or to the dorsal-lateral cell group of III (innervates inferior rectus). This ascending projection terminates rostrally in the nucleus of Darkschewitsch and the interstitial nucleus of Cajal.

II. Lesions in the medial vestibular nucleus and ventral lateral vestibular nucleus

The second group of lesions which produced ascending degeneration from the vestibular nuclei were those involving the more caudal parts of the vestibular complex, specifically the medial vestibular nucleus and the adjacent ventral division of the lateral vestibular nucleus (Deiters). Lesions in this area were created by inserting the probe caudal-ventral to the dorsal acoustic stria and medial to the dorsal surface of the restiform body. It was then passed in a rostral and slightly ventral direction to varying depths into the brainstem.

Since the probe initially passed through the descending (inferior) vestibular nucleus, in almost all cases it was necessary to determine whether this nucleus contributed any ascending fibers to the MLF. Several lesions in this nucleus alone produced degenerating fibers which passed medially and entered both MLF. Ipsilaterally the fibers were located in the dorso-lateral aspect of the MLF (Fig. 45), and contralaterally they were located medially in the bundle.

These degenerated fibers were followed in a descending direction in the MLF but none could be followed to upper levels of the MLF or to the nuclei of IV and III. This indicated that the descending vestibular nucleus did not contribute ascending fibers in the MLF. Others (Carpenter, 1966; Buchanan, 1937) have reported identical findings with regard to the descending nucleus. Any ascending degeneration, therefore, may be correlated with the lesion in the medial and lateral vestibular nuclei.

Cat no 66 (see Fig 36)

This very small lesion involved the dorsal LVN but was located in the lateral portion of the SVN throughout most of its extent (Fig. 37) The rostral pole of the SVN was spared as the lesion was more dorsally positioned and eventually extended into the brachium con junctivum.

A very few degenerating fibers were followed up the MLF to the IV (Fig. 38) and III nuclei and the two rostral nuclei of the ipsilateral side. Noteworthy was the absence of degeneration in the ipsilateral medial cell column of III (Fig 39) thus again correlated with the intact rostral portion of the SVN

The most striking degeneration pattern was that associated with the lesion in the brachium conjunctivum and involved the dorsal part of the contralateral IV nucleus (Fig 38 *B*) and the medial cell column of contralateral III (Fig 39 *A*)

The most important point to be derived from this lesion was that it suggests that the smaller cells that make up the lateral portion of SVN probably do not contribute to the ascending ocular projection This lesion should have injured a significant number [of] these cells by its location The very s[mall] number of ipsilateral degenerating fibers pr[ob]ably belong to a few of the larger cells wh[ich] may be found interspersed with these s[mall] ones in the periphery of the SVN

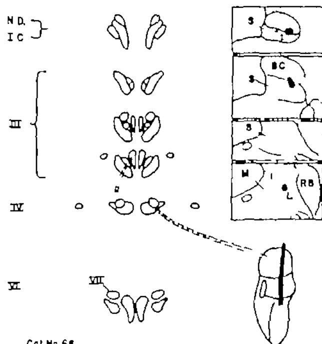

Fig 36

Summary of lesions in SVN

Lesions and degeneration patterns indicated that the superior vestibular nucleus projected only into the ipsilateral MLF where its fibers are located in the lateral half. These fibers terminated in the IV and III nuclei in the following manner: ipsilateral IV bilateral intermediate and ventral lateral cell groups of III with ipsilateral side more marked, ipsilateral medial cell group of III.

Neurons in the caudal-medial part of the SVN project primarily to IV (contralateral superior oblique) and the intermediate lateral cell group of III (ipsilateral inferior oblique). Those in the rostral and central part of SVN project mainly to IV and to the medial cell column (contralateral superior rectus) and ventral-lateral group (ipsilateral medial rectus) of III.

The SVN does not project to the VI nucleus or to the dorsal-lateral cell group of III (innervates inferior rectus). This ascending projection terminates rostrally in the nucleus of Darkschewitsch and the interstitial nucleus of Cajal.

II. *Lesions in the medial vestibular nucleus and ventral lateral vestibular nucleus*

The second group of lesions which produced ascending degeneration from the vestibular nuclei were those involving the more caudal parts of the vestibular complex, specifically the medial vestibular nucleus and the adjacent ventral division of the lateral vestibular nucleus (Deiters). Lesions in this area were created by inserting the probe caudal-ventral to the dorsal acoustic stria and medial to the dorsal surface of the restiform body. It was then passed in a rostral and slightly ventral direction to varying depths into the brainstem.

Since the probe initially passed through the descending (inferior) vestibular nucleus, in almost all cases it was necessary to determine whether this nucleus contributed any ascending fibers to the MLF. Several lesions in this nucleus alone produced degenerating fibers which passed medially and entered both MLF. Ipsilaterally the fibers were located in the dorso-lateral aspect of the MLF (Fig. 45), and contralaterally they were located medially in the bundle.

These degenerated fibers were followed in a descending direction in the MLF but none could be followed to upper levels of the MLF or to the nuclei of IV and III. This indicated that the descending vestibular nucleus did not contribute ascending fibers in the MLF. Others (Carpenter 1966; Buchanan, 1937) have reported identical findings with regard to the descending nucleus. Any ascending degeneration, therefore, may be correlated with the lesion in the medial and lateral vestibular nuclei.

(*B*) Contralateral MLF and trochlear nucleus of Cat 66. Arrows point to a minimal amount of degeneration along dorsal aspect of the nucleus resulting from injury to brachium conjunctivum Cf Fig. 17

Cat no. 98. (Fig. 41)

The lesion in this animal involved a minimal part of the DVN but passed through the lateral most portion of the MVN (Fig. 42) and finally the ventral division of LVN to its rostral pole without injuring the SVN. The olivocochlear bundle was interrupted as it coursed through the ventral LVN (Fig. 43).

Two tracts of degenerating fibers were identified in an ascending direction from the lesion. (1) The main mass of degenerating axons passed directly medially from the MVN lesion and adjacent LVN. These fibers characteristically passed ventral to the facial genu toward the ipsilateral VI nucleus where profuse terminal degeneration was seen (Fig. 44). Degenerating axons destined for the MLF continued past the VI nucleus and either positioned themselves in the dorso-lateral corner of the ipsilateral MLF (Fig. 45) or crossed the midline to assume a dorso-medial location in the contralateral MLF (Fig. 46). The degenerating fibers in the ipsilateral MLF represent descending fiber projections from the DVN and MVN.

The contralateral degeneration in the MLF could be followed to both higher and lower levels of the brainstem and, therefore, probably represent bifurcating axons. The contralateral ascending degenerating fibers retained a medial position in the MLF and terminated in the contralateral IV nucleus (Fig. 47 *A, B*) and the contralateral III nucleus where all the subgroups, except the dorso-lateral one, were found covered with degenerating terminals. Degenerating collaterals crossing the midline within the III nucleus to similar ipsilateral subgroups were again found. Finally these degenerating fibers in the contralateral MLF terminated in the nuclei of Darkschewitsch and Cajal of that side. (2) A number of ipsilateral ascending degenerating fibers were seen as scattered fragmented axons positioned lateral to the ipsilateral MLF (Fig. 48) and arising from the rostral end of the lesion in the ventral LVN. These fibers did not form connections with the ipsilateral IV nucleus but arched medially over the MLF at the level of the III nucleus to terminate only in the dorso-lateral cell group which innervates the inferior rectus muscle (Fig. 49). No degeneration was found in the nuclei of Darkschewitsch or Cajal of this side.

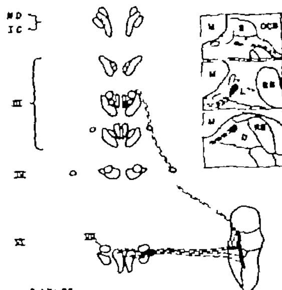

Fig. 41

Cat no. 96 (see Fig 40)

The lesion after passing through the most medial aspect of the DVN extended into the lateral most portion of the medial vestibular nucleus where it adjoins the ventral aspect of the LVN The most rostral extent of the lesion involved a very small part of the caudal end of the ventral LVN Since the DVN does not contribute any ascending fibers to the MLF the degeneration in this bundle can be considered to be from the MVN

Degenerating fibers passed directly medially from the lesion and coursed under the genu of the facial nerve. Some fibers at this point terminated in the ipsilateral VIth nucleus either by collaterals or by termination of a parent fiber The majority of the fibers passed through or above the MLF to become located in the dorso-medial aspect of the contralateral MLF and the lateral aspect of the ipsilateral MLF

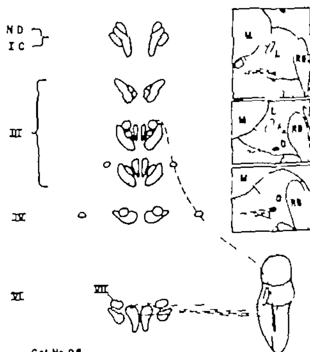

Fig 40

Only the degenerating fibers in the contralateral MLF could be found in higher levels of the MLF and therefore represented the ascending degeneration from this lesion. They characteristically occupied a more medial position in the MLF than the fibers from the SVN Preterminal degeneration was found in the contralateral IV and III nuclei Degeneration in the contralateral oculomotor complex involved the intermediate and ventral-lateral cell groups while the dorsal-lateral group and the medial cell column were completely free However a small but definite amount of fine degenerating preterminals was found ipsilaterally in only the dorsal lateral cell group of III. These fibers did not arise from the ipsilateral MLF but from a pathway outside and lateral to this bundle. A few degenerating fibers were seen in this area and followed caudally to the region of the lesion

The most rostral preterminal degeneration was seen in the contralateral nucleus of Darkschewitsch and the interstitial nucleus of Cajal and represented the rostral termination of the degenerating fibers in the contralateral MLF

Cat no. 98 (Fig. 41)

The lesion in this animal involved a minimal part of the DVN but passed through the lateral most portion of the MVN (Fig. 42) and finally the ventral division of LVN to its rostral pole without injuring the SVN. The olivocochlear bundle was interrupted as it coursed through the ventral LVN (Fig. 43).

Two tracts of degenerating fibers were identified in an ascending direction from the lesion. (1) The main mass of degenerating axons passed directly medially from the MVN lesion and adjacent LVN. These fibers characteristically passed ventral to the facial genu toward the ipsilateral VI nucleus where profuse terminal degeneration was seen (Fig. 44). Degenerating axons destined for the MLF continued past the VI nucleus and either positioned themselves in the dorso-lateral corner of the ipsilateral MLF (Fig. 45) or crossed the midline to assume a dorso-medial location in the contralateral MLF (Fig. 46). The degenerating fibers in the ipsilateral MLF represent descending fiber projections from the DVN and MVN.

The contralateral degeneration in the MLF could be followed to both higher and lower levels of the brainstem and, therefore, probably represent bifurcating axons. The contralateral ascending degenerating fibers retained a medial position in the MLF and terminated in the contralateral IV nucleus (Fig. 47 *A*, *B*), and the contralateral III nucleus where all the subgroups, except the dorso-lateral one were found covered with degenerating terminals. Degenerating collaterals crossing the midline within the III nucleus to similar ipsilateral subgroups were again found. Finally these degenerating fibers in the contralateral MLF terminated in the nuclei of Darkschewitsch and Cajal of that side. (2) A number of ipsilateral ascending degenerating fibers were seen as scattered fragmented axons positioned lateral to the ipsilateral MLF (Fig. 48) and arising from the rostral end of the lesion in the ventral LVN. These fibers did not form connections with the ipsilateral IV nucleus but arched medially over the MLF at the level of the III nucleus to terminate only in the dorso-lateral cell group which innervates the inferior rectus muscle (Fig. 49). No degeneration was found in the nuclei of Darkschewitsch or Cajal of this side.

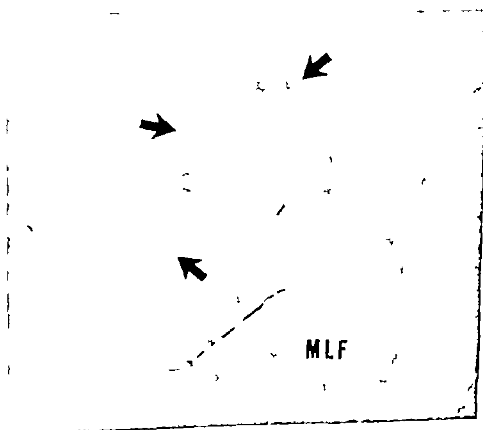

Fig 49 High power view of the ipsilateral oculomotor nucleus of Cat 98. Arrows point out degeneration in the dorso-lateral group which is supplied by the ascending tract of Deiters. Note the absence of degeneration in the nuclear zones to the left and inferior to the dorso-lateral group.

Cat no. 100 (see Fig 50)

The lesion in this animal was similar to that in the previous animal but was larger in diameter and more laterally placed in the ventral lateral vestibular nucleus (Fig. 51).

At the level of the facial genu degenerating fibers were followed medially from the lesion and passed ventral to the facial nerve *to enter the lateral aspect of the ipsilateral* MLF and the dorso-medial corner of the contralateral MLF. The degenerating fibers in the *ipsilateral MLF represent descending* projections from the descending and medial vestibular nuclei while those in the contralateral MLF are the fibers of the ascending system from the medial nucleus. Many of these contralateral degenerating fibers bifurcate and send a descending branch as well in the MLF.

Preterminal degeneration from these degenerating fibers entering the MLF was found mainly in the ipsilateral VI nucleus but also in the contralateral VI nucleus. The degenerating fibers at higher levels of the MLF were found in the medial portion of only the contralateral bundle. Fine terminal and preterminal degeneration was observed in the contralateral IV, III (intermediate and ventral-lateral cell groups, and medial cell group) and the nuclei of Darkschewitsch and Cajal.

The dorsal-lateral cell column of the con-

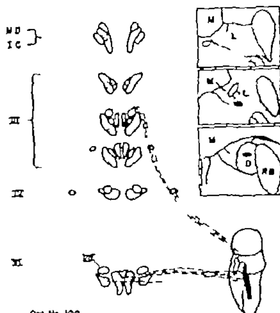

Fig 50

Fig 48. High power of the area lateral t ipsilateral MLF show Fig. 47 *B* Arrows out an area of scattere generated fibers whic outside the lateral lin the MLF These fibers resent the ascending of Deiters"

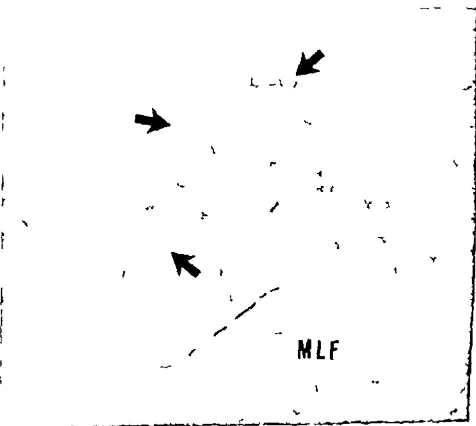

Fig 49 High power of the ipsilateral oculo tor nucleus of Cat *Arrows point out dege ation in the dorso-lat group which is supplied the ascending tract Deiters. Note the abse of degeneration in the* clear zones to the left inferior to the dorso-la al group

tralateral III nucleus was conspicuously free of degeneration while the same subnuclear group on the ipsilateral side was covered with a more significant amount of preterminal degeneration than in cat Number 98 (Fig. 52 *A B*). Degenerating fibers supplying this ipsilateral group were definitely seen ascending from the rostral end of the lesion in the lateral vestibular nucleus to travel ventral to the superior vestibular nucleus and then gradually assumed a position in the brainstem lateral to the MLF until the level of the III nucleus was reached. The fibers then arched over the dorso-lateral aspect of the MLF to terminate in the dorsal-lateral cell group. This tract of degenerating fibers would appear to correspond to the ascending tract of Deiters" of Winkler (1918) Buchanan (1937) and to the vestibulo-tegmentalis lateralis" of Muskens (1913–14).

The lesions in animals 98 and 100 confirmed the course and origin from the MVN of the contralateral ascending ocular projection in the MLF and by involving more of the ventral part of the lateral vestibular nucleus than cat Number 96 clearly demonstrated the source of the degenerating fibers to the ipsilateral dorsal-lateral cell group of the III nucleus. The projection of this area (MVN and LVN) to both VI nuclei but in a predominantly ipsilateral fashion was also demonstrated by this larger lesion.

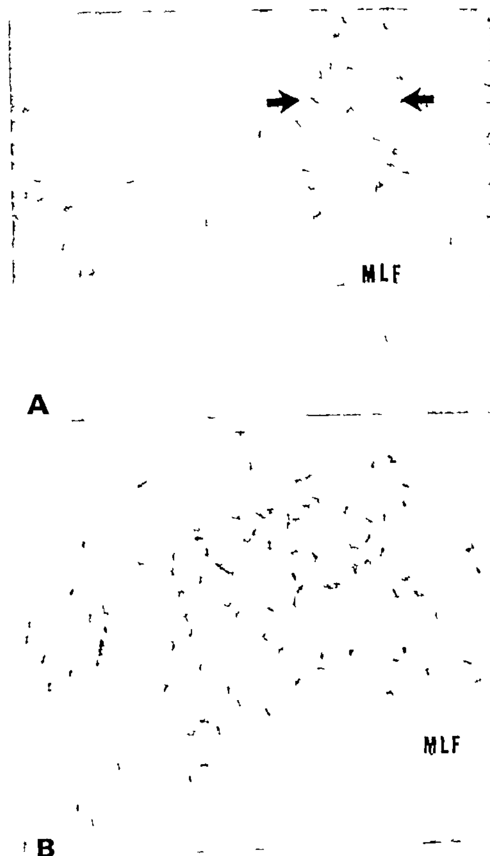

Fig. 52 (A) Low power view of oculomotor nucleus in Cat 100. Arrows mark the pallateral dorsolateral cell group which is covered with terminal degeneration shown to better advantage in next figure. Note also the diffuse degener tion throughout the contralateral (*left*) side of the nucleus. (B) High power view of the area marked by arrow i preceding figure

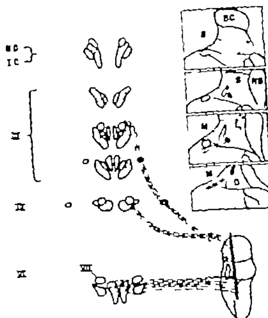

Fig 55

clear complex, and the contralateral nuclei of Darkschewitsch and Cajal.

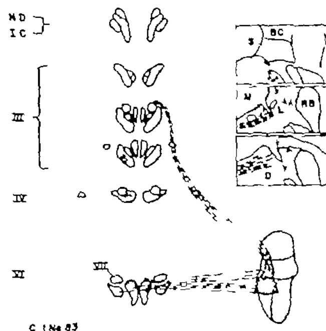
Lesions in the ventral division of the lateral vestibular nucleus confirmed its descending projection in the ipsilateral vestibulo-spinal tract but also proved that it has connections with the ipsilateral oculomotor (III) nucleus but not to the trochlear (IV) nucleus. The projection to the oculomotor complex was quite unique because it terminated in the only cell group that neither the ipsilateral nor contralateral MLF ascending pathways formed connections with. Since the lateral nucleus (Deiters) projected its ascending fibers in a tract lateral to the MLF it seemed quite appropriate to retain the terminology "ascending tract of Deiters" as used by Winkler (1918) and Buchanan (1937).

Summary of lesions in the medial vestibular nucleus and ventral lateral vestibular nucleus

Lesions in this group of animals indicated that the area of small cells just ventral to the caudal-ventral end of the lateral vestibular nucleus probably represents an extension of the rostral part of the medial vestibular nucleus because its projections are identical to those of the medial vestibular nucleus. These experimental animals indicated that this nucleus sends fibers primarily into the dorsal medial aspect of the contralateral MLF. As these axons pass toward the MLF they make connections with both abducens (VI) nuclei. The fibers that reach the contralateral MLF may send a branch in a descending direction toward the cord levels but for the most part they ascend in the medial portion of the MLF to terminate with the contralateral IV nucleus, the contralateral subdivisions (except for the dorsal-lateral cell group) and to a lesser degree the ipsilateral subgroups of the III nu-

III. *Lesions in the medial lateral and superior vestibular nuclei*

The lesion in Animals 89 (Fig. 55) and 90 (Fig. 54) involved all three of the vestibular nuclei that give ascending projections to the extra-ocular nuclei and, therefore, give a summation of these connections. Both these animals can be discussed together stressing several points.



Although the lesion in Animal 90 is larger in diameter (as evidenced by more degeneration from the superior vestibular nucleus), it was more dorsally located in the caudal area, thus injuring cells in the *ventral division of* LVN but barely injured the medial vestibular nucleus while in Animal 89 the more ventral location of the lesion significantly injured this area of MVN. The significant corresponding difference in the degeneration patterns occurred in the contralateral ascending MLF system where the minimal degeneration in the contralateral MLF and the contralateral abducens (VI) nucleus of Animal 90 confirmed that the medial vestibular nucleus and not the lateral vestibular nucleus is mainly responsible for this contralateral projection in the MLF

Cat no. 83 (see Fig 53)

The lesion in this animal was made by a small knife made of a sliver of razor blade. By depressing the knife ventro-laterally through the medial aspect of the dorsal acoustic stria, the entire width of the medial vestibular nucleus and a larger segment of the ventral LVN were involved in the lesion Thus the neurons in the medial portion of the MVN that escaped injury in the previous animals with small, more laterally placed lesions, were now transected. The degeneration pattern was identical to previous animals. However the amount of degeneration in the contralateral ascending system in the MLF was significantly greater indicating that most, if not all, of the rostral half of MVN contributes to the contralateral ascending projection. This further justifies including in the medial vestibular nucleus the area of smaller neurons just ventral to the ventral division of LVN and lateral to the dorsal acoustic stria, rather than in the descending vestibular nucleus (DVN) (Gacek 1969) or lateral vestibular nucleus (LVN) (Fraser 1902, Muskens, 1913–14).

The bilateral but asymmetrical projections to the VI nuclei were also confirmed by this lesion. The ipsilateral nucleus received, by far the greater portion of this projection. It is not possible to precisely say however the degree to which MVN or ventral LVN contribute to these nuclei but the medial nucleus probably gives rise to most of these fiber connections.

Collaterals of the contralateral ascending MLF system that crossed the midline within the III complex were observed as they were in the ipsilateral MLF projection from the superior vestibular nucleus. This finding was also present in the III complex in Animal 98. The degeneration in the "ascending tract of Deiters" which terminated in the ipsilateral dorsal-lateral cell group of III was observed again as in previous animals. The fact that the very rostral end of the lesion undercut the superior vestibular nucleus without damaging it was proved by the absence of any degeneration in the ipsilateral MLF

F g 53

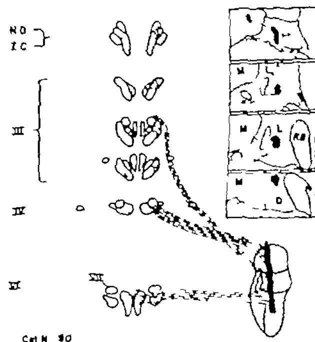


Fig 54

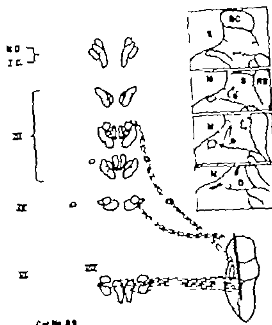

Fig 55

clear complex, and the contralateral nuclei of Darkschewitsch and Cajal.

Lesions in the ventral division of the lateral vestibular nucleus confirmed its descending projection in the ipsilateral vestibulo-spinal tract but also proved that it has connections with the ipsilateral oculomotor (III) *nucleus* but not to the trochlear (IV) *nucleus*. The projection *to the oculomotor* complex was quite *unique because* it terminated in the only cell group that neither the ipsilateral nor contralateral MLF ascending pathways formed connections with. Since the lateral nucleus (Deiters) projected its ascending fibers in a tract lateral to the MLF it seemed quite appropriate to retain *the terminology* ascending *tract of* Deiters" as used by Winkler (1918) and Buchanan (1937).

Summary of lesions in the medial vestibular nucleus and ventral lateral vestibular nucleus

Lesions in this group of animals indicated that the area of small cells just ventral to the caudal-ventral end *of* the lateral vestibular nucleus probably represents an extension of the rostral part of the medial vestibular nucleus because its projections are identical to those of the medial vestibular nucleus. These experimental animals *indicated that this nucleus* sends fibers primarily into the dorsal medial aspect of the contralateral MLF As these axons pass toward the MLF they make connections with both abducens (VI) nuclei. The *fibers* that reach the contralateral MLF may send a *branch to a descending direction* toward the cord levels but for the most *part* they ascend in the medial portion of the MLP to terminate with. the contralateral IV nucleus, the contralateral subdivisions (except for *the dorsal-lateral cell group)* and *to* a lesser degree the ipsilateral subgroups of the III nu-

III. *Lesions in the medial lateral and superior vestibular nuclei*

The lesion in Animals 89 (Fig. 55) and 90 (Fig. 54) involved all three of the vestibular nuclei that give ascending projections to the extra-ocular nuclei and, therefore, give a summation of these connections. Both these *animals can be discussed together stressing* several points.

Although the lesion in Animal 90 is larger in diameter (as evidenced by more degeneration from the superior vestibular nucleus), it was more dorsally located in the caudal area, *thus injuring cells in the ventral division of LVN but barely injured the medial* vestibular nucleus while in Animal 89 the more ventral location of the lesion significantly injured this area of MVN The significant corresponding difference in the degeneration patterns occurred in the contralateral ascending MLF sys*tem where the minimal* degeneration in the contralateral *MLF and the contralateral* abducens (VI) nucleus of Animal 90 *confirmed* that the medial vestibular nucleus and not the lateral vestibular nucleus is mainly responsible for this contralateral projection in the MLF

Fig 56 (A, B) High power views of the ipsilateral (A) and contralateral (B) MLF and trochlear nuclei of Cat 89 showing degeneration of fibers in both ascending systems in the MLF and terminal degeneration in both trochlear nuclei (4)

Fig. 57. High power view of the ipsilateral oculomotor nucleus of Cat 89 showing how degenerated fibers from the ascending tract of Deiters arch over the MLF to terminate in the dorso-lateral group of the nucleus.

Because both ascending MLF systems (fig. 56 *A*, *B*) and the ipsilateral ascending tract of Deiters (Fig. 57) were involved in these animals the degeneration pattern in the oculomotor (III) complex was interesting to examine. All subdivisions of the oculomotor complex except for the contralateral dorsal-lateral cell group (which is innervated by the contralateral lateral vestibular nucleus) were covered with degeneration. This means that all the extraocular muscles of both sides except for the contralateral inferior rectus receive direct innervation from each vestibular nuclear complex or labyrinth.

Fig 56 (*A B*) High power views of the ipsilateral (*A*) and contralateral (*B*) MLF and trochlear nuclei of Cat 89 showing degeneration of fibers in both ascending systems in the MLF and terminal degeneration in both trochlear nuclei (*4*)

this has been designated as descending vestibular nucleus (Gacek 1969) or ventral part of lateral vestibular nucleus (Mutkens, 1913–14) but in terms of its output it should rightfully be included in the medial vestibular nucleus. Studies on the termination of primary vestibular neurons indicated that the descending branches of incoming fibers from the cristae and the maculae terminate in this area to a large degree.

The fibers of this ascending system projected to and terminated in the contralateral trochlear nucleus and the contralateral divisions of the oculomotor complex in a similar fashion to the innervation pattern of the ipsilateral ascending system from the superior vestibular nucleus. The rostral terminus of this system also concerned the interstitial nucleus of Cajal and the nucleus of Darkschewitsch. The contralateral ascending system was also devoid of termination in the cell group (dorso-lateral) of the oculomotor complex which supplies the inferior rectus muscle.

It appears then that the two ascending systems in the MLF arise from the superior and the medial vestibular nuclei and project in a balanced fashion up the two sides of the brain stem to similar areas of termination in the III and IV cranial nerve nuclei. Rostral terminations in the midbrain nuclei of Darkschewitsch and Cajal are also similar.

(b) The third system of ascending fibers projected only to the oculomotor (III) complex and was not located in the MLF. It coursed in a less discrete tract which occupied the lateral part of the brainstem and midbrain. In the midbrain area it traveled just lateral to the lateral wing of the MLF. This tract has been called the "ascending tract of Deiters" in older literature indicating that its origin is from the lateral vestibular nucleus or nucleus of Deiters. Mutkens (1914) who originally described this tract felt that it originated from medium cells in the dorsal division of Deiters while Buchanan (1937) concluded that the ventral portion of Deiters was the source of this system. Previous descriptions, however, have not described precise termination of this tract because of the limitation of the Marchi method to myelinated portions of nerve fibers.

In this study the origin of this tract from the ventral division of the lateral vestibular nucleus was confirmed. This finding would explain Brodal's (1957) description of absence of changes in some cells of the rostro-ventral part of LVN when the vestibulo-spinal tract was sectioned high in the cervical region. The large multipolar neurons in the dorsal and caudal regions of the LVN exhibited characteristic retrograde reaction changes following such a lesion indicating that they contribute to the vestibulo-spinal tract. The unchanged neurons in the ventral division of LVN probably represent those that contribute to the "ascending tract of Deiters".

The ultimate termination of this tract in the cell group of III which innervates the ipsilateral inferior rectus muscle was clear cut and consistent. No evidence of termination in the trochlear (IV) nucleus or the rostral nuclei of Darkschewitsch and Cajal was found.

II. Abducens (VI) nuclei

Connections to the abducens nuclei appeared to come only from lesions in the mid and caudal areas of the vestibular complex. Ipsilateral and contralateral connections to these nuclei were found from the medial vestibular nucleus (see Cats 89 and 100) and *primarily* ipsilateral connections to the nucleus were found from the descending vestibular nucleus. The descending vestibular nucleus, as far as could be determined from lesions isolated in it, contributed only descending projections in both medial longitudinal fasciculi.

These results can explain the findings of physiological studies such as the one of Tokumasu et al. (1969) which had been reviewed earlier. They found that a stimulating electrode in the superior vestibular nucleus produced upward, rotatory and some horizontal eye movements but no downward eye movements. The present study has demonstrated

Discussion

A VESTIBULO-OCULAR PROJECTIONS

I *Trochlear (IV) and oculomotor (III) nuclei*

Three systems of ascending fibers from the vestibular nuclei to the IV and III cranial nerve nuclei were demonstrated in this study

(*a*) Two of these tracts were carried via the medial longitudinal fasciculus

(1) The ascending projection via the ipsilateral MLF was located in the lateral portion of the bundle These fibers arose entirely from the superior vestibular nucleus and terminated in the ipsilateral trochlear nucleus as well as all the ipsilateral and contralateral subdivisions except the dorso-lateral group of the oculomotor complex. The contralateral connections of the SVN in the oculomotor nucleus were clearly carried by fine fibers crossing the midline within the complex and not by fibers ascending in the contralateral MLF Only the dorso-lateral cell portion of the oculomotor nucleus did not receive innervation from this ipsilateral system. This tract of fibers from the SVN ultimately terminated in the ipsilateral interstitial nucleus of Cajal and the nucleus of Darkschewitsch at rostral midbrain levels.

Since the superior vestibular nucleus receives its peripheral input only from the semicircular canals the possibility of an organization of this ascending tract according to canals was considered. A difference in projection of the portion of the SVN (caudo-medial) which receives input from the posterior canal and that portion of the nucleus (rostral-lateral) which is innervated by the horizontal and superior canals was suggested

The caudal and medial part of the SVN projected primarily to the intermediate lateral cell group of the ipsilateral oculomotor nucleus and also to the trochlear nucleus of the same side By way of these connections the most pronounced muscle contractions from input to this part of the SVN would be the ipsilateral inferior oblique and the contralateral superior oblique muscles. These produce primarily a rotational movement in an ampullopetal direction to the posterior semicircular canal. Rotatory nystagnoid ocular movements clinically are usually associated with stimulation of the posterior semi-circular canal as in benign paroxysmal vertigo of peripheral type (Lindsay & Hemenway 1956 Schuknecht, 1962)

The rostral and lateral portions of the SVN projected mainly to the ipsilateral medial cell column and the intermediate ventral cell columns of III along with the ipsilateral trochlear (IV) nucleus. These nuclei of III innervate the contralateral superior rectus, the ipsilateral inferior oblique and ipsilateral medial rectus muscles. The combination of rotatory and vertical eye movements brought about by these muscles could correlate with the termination of the superior semi-circular canal and the horizontal movement of the medial rectus (and the inferior oblique) could correspond to horizontal canal connection in this part of the superior vestibular nucleus.

(2) The second system which projected in an ascending direction by way of the MLF was the contralateral one coursing in the medial portion of the contralateral MLF to the III and IV cranial nerve nuclei. The lesions in this study indicated that this fiber system arose from cells in the rostral portion of the medial vestibular nucleus. In previous studies

this has been designated as descending vestibular nucleus (Gacek 1969) or ventral part of lateral vestibular nucleus (Muskens, 1913–14) but in terms of its output it should rightfully be included in the medial vestibular nucleus. Studies on the termination of primary vestibular neurons indicated that the descending branches of incoming fibers from the cristae and the maculae terminate in this area to a large degree.

The fibers of this ascending system projected to and terminated in the contralateral trochlear nucleus and the contralateral divisions of the oculomotor complex in a similar fashion to the innervation pattern of the ipsilateral ascending system from the superior vestibular nucleus. The rostral terminus of this system also concerned the interstitial nucleus of Cajal and the nucleus of Darkschewitsch. The contralateral ascending system was also devoid of termination in the cell group (dorso-lateral) of the oculomotor complex which supplies the inferior rectus muscle.

It appears then that the two ascending systems in the MLF arise from the superior and the medial vestibular nuclei and project in a balanced fashion up the two sides of the brainstem to similar areas of termination in the III and IV cranial nerve nuclei. Rostral terminations in the midbrain nuclei of Darkschewitsch and Cajal are also similar.

(*b*) The third system of ascending fibers projected only to the oculomotor (III) complex and was not located in the MLF. It coursed in a less discrete tract which occupied the lateral part of the brainstem and midbrain. In the midbrain area it traveled just lateral to the lateral wing of the MLF. This tract has been called the "ascending tract of Deiters" in older literature, indicating that its origin is from the lateral vestibular nucleus or nucleus of Deiters. Muskens (1914) who originally described this tract felt that it originated from medium cells in the dorsal division of Deiters while Buchanan (1937) concluded that the ventral portion of Deiters was the source of this system. Previous descriptions, however, have not described precise termination of this tract because of the limitation of the Marchi method to myelinated portions of nerve fibers.

In this study the origin of this tract from the ventral division of the lateral vestibular nucleus was confirmed. This finding would explain Brodal's (1957) description of absence of changes in some cells of the rostro-ventral part of LVN when the vestibulo-spinal tract was sectioned high in the cervical region. The large multipolar neurons in the dorsal and caudal regions of the LVN exhibited characteristic retrograde reaction changes following such a lesion indicating that they contribute to the vestibulo-spinal tract. The unchanged neurons in the ventral division of LVN probably represent those that contribute to the "ascending tract of Deiters".

The ultimate termination of this tract in the cell group of III which innervates the ipsilateral inferior rectus muscle was clear cut and consistent. No evidence of termination in the trochlear (IV) nucleus or the rostral nuclei of Darkschewitsch and Cajal was found.

II. *Abducens (VI) nuclei*

Connections to the abducens nuclei appeared to come only from lesions in the mid and caudal areas of the vestibular complex. Ipsilateral and contralateral connections to these nuclei were found from the medial vestibular nucleus (see Cats 89 and 100) and primarily ipsilateral connections to the nucleus were found from the descending vestibular nucleus. The descending vestibular nucleus, as far as could be determined from lesions isolated in it, contributed only descending projections to both medial longitudinal fasciculi.

These results can explain the findings of physiological studies such as the one of Tokumasu et al. (1969) which had been reviewed earlier. They found that a stimulating electrode in the superior vestibular nucleus produced upward, rotatory and some horizontal eye movements but no downward eye movements. The present study has demonstrated

A. VESTIBULO-OCULAR PROJECTIONS

I. *Trochlear (IV) and oculomotor (III) nuclei*

Three systems of ascending fibers from the vestibular nuclei to the IV and III cranial nerve nuclei were demonstrated in this study.

(*a*) Two of these tracts were carried via the medial longitudinal fasciculus.

(*1*) The ascending projection via the ipsilateral MLF was located in the lateral portion of the bundle. These fibers arose entirely from the superior vestibular nucleus and terminated in the ipsilateral trochlear nucleus as well as all the ipsilateral and contralateral subdivisions except the dorso-lateral group of the oculomotor complex. The contralateral connections of the SVN in the oculomotor nucleus were clearly carried by fine fibers crossing the midline within the complex and not by fibers ascending in the contralateral MLF. Only the dorso-lateral cell portion of the oculomotor nucleus did not receive innervation from this ipsilateral system. This tract of fibers from the SVN ultimately terminated in the ipsilateral interstitial nucleus of Cajal and the nucleus of Darkschewitsch at rostral midbrain levels.

Since the superior vestibular nucleus receives its peripheral input only from the semicircular canals, the possibility of an organization of this ascending tract according to canals was considered. A difference in projection of the portion of the SVN (caudo-medial) which receives input from the posterior canal and that portion of the nucleus (rostral lateral) which is innervated by the horizontal and superior canals was suggested.

The caudal and medial part of the SVN projected primarily to the intermediate lateral cell group of the ipsilateral oculomotor nucleus and also to the trochlear nucleus of the same side. By way of these connections the most pronounced muscle contractions from input to this part of the SVN would be the ipsilateral inferior oblique and the contralateral superior oblique muscles. These produce *primarily* a rotational movement in an ampullopetal direction to the posterior semicircular canal. Rotatory nystagnoid ocular movements clinically are usually associated with stimulation of the posterior semi-circular canal as in benign paroxysmal vertigo of peripheral type (Lindsay & Hemenway 1956 Schuknecht, 1962).

The rostral and lateral portions of the SVN projected mainly to the ipsilateral medial cell column and the intermediate ventral cell columns of III along with the ipsilateral trochlear (IV) nucleus. These nuclei of III innervate the contralateral superior rectus, the ipsilateral inferior oblique and ipsilateral medial rectus muscles. The combination of rotatory and vertical eye movements brought about by these muscles could correlate with the termination of the superior semi-circular canal and the horizontal movement of the medial rectus (and the inferior oblique) could correspond to horizontal canal connection in this part of the superior vestibular nucleus.

(2) The second system which projected in an ascending direction by way of the MLF was the contralateral one coursing in the medial portion of the contralateral MLF to the III and IV cranial nerve nuclei. The lesions in this study indicated that this fiber system arose from cells in the rostral portion of the medial vestibular nucleus. In previous studies

this has been designated as descending vestibular nucleus (Gacek 1969) or ventral part of lateral vestibular nucleus (Muskens, 1913–14) but in terms of its output it should rightfully be included in the medial vestibular nucleus. Studies on the termination of primary vestibular neurons indicated that the descending branches of incoming fibers from the cristae and the maculae terminate in this area to a large degree.

The fibers of this ascending system projected to and terminated in the contralateral trochlear nucleus and the contralateral divisions of the oculomotor complex in a similar fashion to the innervation pattern of the ipsilateral ascending system from the superior vestibular nucleus. The rostral terminus of this system also concerned the interstitial nucleus of Cajal and the nucleus of Darkschewitsch. The contralateral ascending system was also devoid of termination in the cell group (dorso-lateral) of the oculomotor complex which supplies the inferior rectus muscle.

It appears then that the two ascending systems in the MLF arise from the superior and the medial vestibular nuclei and project in a balanced fashion up the two sides of the brainstem to similar areas of termination in the III and IV cranial nerve nuclei. Rostral terminations in the midbrain nuclei of Darkschewitsch and Cajal are also similar.

(b) The third system of ascending fibers projected only to the oculomotor (III) complex and was not located in the MLF. It coursed in a less discrete tract which occupied the lateral part of the brainstem and midbrain. In the midbrain area it traveled just lateral to the lateral wing of the MLF. This tract has been called the "ascending tract of Deiters" in older literature, indicating that its origin is from the lateral vestibular nucleus or nucleus of Deiters. Muskens (1914) who originally described this tract felt that it originated from medium cells in the dorsal division of Deiters while Buchanan (1937) concluded that the ventral portion of Deiters was the source of this system. Previous descriptions, however, have not described precise termination of this tract because of the limitation of the Marchi method to myelinated portions of nerve fibers.

In this study the origin of this tract from the ventral division of the lateral vestibular nucleus was confirmed. This finding would explain Brodal's (1957) description of absence of changes in some cells of the rostro-ventral part of LVN when the vestibulo-spinal tract was sectioned high in the cervical region. The large multipolar neurons in the dorsal and caudal regions of the LVN exhibited characteristic retrograde reaction changes following such a lesion indicating that they contribute to the vestibulo-spinal tract. The unchanged neurons in the ventral division of LVN probably represent those that contribute to the ascending tract of Deiters".

The ultimate termination of this tract in the cell group of III which innervates the ipsilateral inferior rectus muscle was clear cut and consistent. No evidence of termination in the trochlear (IV) nucleus or the rostral nuclei of Darkschewitsch and Cajal was found.

II. *Abducens (VI) nuclei*

Connections to the abducens nuclei appeared to come only from lesions in the mid and caudal areas of the vestibular complex. Ipsilateral and contralateral connections to these nuclei were found from the medial vestibular nucleus (see Cats 89 and 100) and primarily ipsilateral connections to the nucleus were found from the descending vestibular nucleus. The descending vestibular nucleus, as far as could be determined from lesions isolated in it, contributed only descending projections in both medial longitudinal fasciculi.

These results can explain the findings of physiological studies such as the one of Tokumasu et al. (1969) which had been reviewed earlier. They found that a stimulating electrode in the superior vestibular nucleus produced upward, rotatory and some horizontal eye movements but no downward eye movements. The present study has demonstrated

A VESTIBULO–OCULAR PROJECTIONS

I. *Trochlear (IV) and oculomotor (III) nuclei*

Three systems of ascending fibers from the vestibular nuclei to the IV and III cranial nerve nuclei were demonstrated in this study

(*a*) Two of these tracts were carried via the medial longitudinal fasciculus.

(1) The ascending projection via the ipsilateral MLF was located in the lateral portion of the bundle These fibers arose entirely from the superior vestibular nucleus and terminated in the ipsilateral trochlear nucleus as well as all the ipsilateral and contralateral subdivisions except the dorso-lateral group of the oculomotor complex. The contralateral connections of the SVN in the oculomotor nucleus were clearly carried by fine fibers crossing the midline within the complex and not by fibers ascending in the contralateral MLF Only the dorso-lateral cell portion of the oculomotor nucleus did not receive innervation from this ipsilateral system. This tract of fibers from the SVN ultimately terminated in the ipsilateral interstitial nucleus of Cajal and the nucleus of Darkschewitsch at rostral mid brain levels.

Since the superior vestibular nucleus receives its peripheral input only from the semicircular canals, the possibility of an organization of this ascending tract according to canals was considered. A difference in projection of the portion of the SVN (caudo-medial) which receives input from the posterior canal and that portion of the nucleus (rostral-lateral) which is innervated by the horizontal and superior canals was suggested

The caudal and medial part of the SVN projected primarily to the intermediate lateral cell group of the ipsilateral oculomotor nucleus and also to the trochlear nucleus of the same side. By way of these connections the most pronounced muscle contractions from input to this part of the SVN would be the ipsilateral inferior oblique and the contralateral superior oblique muscles. These produce primarily a rotational movement in an ampullopetal direction to the posterior semicircular canal. Rotatory nystagnoid ocular movements clinically are usually associated with stimulation of the posterior semi-circular canal as in benign paroxysmal vertigo of peripheral type (Lindsay & Hemenway 1956 Schuknecht 1962)

The rostral and lateral portions of the SVN projected mainly to the ipsilateral medial cell column and the intermediate ventral cell columns of III along with the ipsilateral trochlear (IV) nucleus. These nuclei of III innervate the contralateral superior rectus, the ipsilateral inferior oblique and ipsilateral medial rectus muscles. The combination of rotatory and vertical eye movements brought about by these muscles could correlate with the termination of the superior semi-circular canal and the horizontal movement of the medial rectus (and the inferior oblique) could correspond to horizontal canal connection in this part of the superior vestibular nucleus.

(2) The second system which projected in an ascending direction by way of the MLF was the contralateral one coursing in the medial portion of the contralateral MLF to the III and IV cranial nerve nuclei The lesions in this study indicated that this fiber system arose from cells in the rostral portion of the medial vestibular nucleus. In previous studies

MACULAE

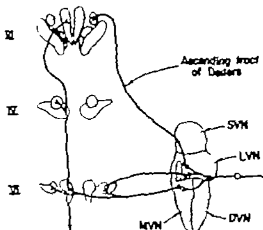

Fig. 59 Diagram summarizing the ascending pathways that may be activated by first order neurons from the maculae of utricle or saccule.

itory while the other is facilitatory allowing for a unidirectional eye movement.

In the second diagram (Fig. 59) a summary of the fibers from the otolithic sense organs, (utricle and saccule) could be represented by a fiber which has an ascending branch terminating in the ventral division of the lateral vestibular nucleus and a descending one terminating in the rostral portion of the medial vestibular nucleus. Compensatory eye movements whether they be horizontal or vertical from utricular stimulation or the theoretical vertical movements from saccular stimulation could be carried out by the systems in this diagram. For example, stimulation of the lateral rectus and medial rectus muscles via the direct connections of the medial and lateral vestibular nuclei to the abducens (VI) and to the medial rectus (III) via the ascending contralateral system is evident. Movements of the inferior rectus by way of the ascending tract of Deiters and the superior rectus by way of the contralateral MLF system from the medial vestibular nucleus could be the pathway for vertical eye movements from stimulation of the saccule or vertical portion of the utricle.

C. DIRECT CEREBELLAR CONNECTIONS TO THE EYE NUCLEI

The interesting and unique direct cerebellar projection to the trochlear (IV) nucleus and oculomotor (III) complex that was demonstrated in the control group confirmed the previous finding of Carpenter & Strominger (1964) and others (Allen, 1924 Van Gehuchten 1905 Gerebtzoff 1936, 1941 Klimoff 1898, 1899 Rasmussen, 1932). A clear demonstration of fibers of cerebellar origin coursing through the brachium conjunctivum was found terminating in the contralateral cells of the medial cell column of the oculomotor (III) complex and in a small portion of the contralateral trochlear (IV) nucleus. These innervate the ipsilateral superior rectus and superior oblique muscles respectively. Fibers reached these nuclear groups by passing in a dorsal direction from the region of the contralateral Red Nucleus and filtering at right angles through the longitudinally running fibers of the MLF.

The functional significance of this fiber connection is not clear but, as it is a unique connection, it is interesting to speculate on its significance. For example, the tremendous number of cerebellar fibers terminating in the superior rectus muscle group may be responsible for strong inhibition of this group and perhaps making movements in this direction less apparent upon peripheral stimulation, such as from stimulation of the saccule.

D. PROJECTIONS TO RETICULAR FORMATION

The various lesions in this group of animals consistently produced significant degeneration to the ipsilateral reticular formation. In most cases precise terminal and preterminal degeneration patterns around the larger neurons could be found (Fig. 60). This connection points up the well-known relationship between the vestibular system and the reticular

that the SVN projected to all the muscles supplied by nuclei III and IV except for the inferior rectus. This explains the absence of downward eye movements from stimulation in this nucleus.

Placement of the stimulating electrode in the middle portions of the vestibular complex which included the lateral vestibular nucleus and the rostral pole of the medial vestibular nucelus, produced upward rotatory horizontal and downward rotatory eye movements. Here the resulting eye reflexes were probably carried over the contralateral MLF ascending system to III and IV for upward rotatory movements, the projections to the abducens (VI) nuclei for horizontal movements, and over the ascending tract of Deiters to the inferior rectus group of III for downward eye movements.

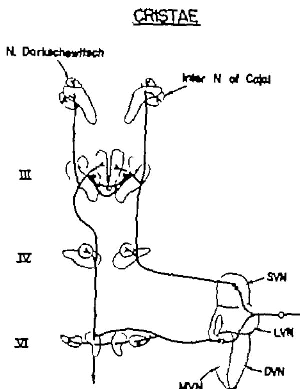

Fig 58 Diagram summarizing the ascending pathways that may be activated by first order neuron from the semicircular canal cristae.

B LABYRINTHINE-OCULAR PATHWAYS

Utilizing the data of previous studies which determined the termination in the vestibular nuclei of *primary* neurons from both the cristae and the maculae, two (2) summary diagrams correlating these ascending ocular systems with peripheral sense organs can be constructed.

In Fig. 58 the primary neuron from a semicircular canal crista is represented as a bifurcating nerve fiber sending an ascending branch to the superior vestibular nucleus and a descending one which terminates mainly in the rostral portion of the medial vestibular nucleus. These two nuclei connect the semicircular canal neurons to the III IV and VI nerve nuclei by way of the ipsilateral and contralateral ascending systems in the medial longitudinal fasciculi

The similarity in size and termination of the two ascending projections from the incoming first order neurons from cristae would appear difficult to understand in terms of eye movements in a particular direction. However there are several features of these pathways that would allow for well-coordinated directional eye movements from semi-circular canal stimulation Of course the distribution of fibers in each ascending system to nuclei supplying several eye muscles would indicate that probably several eye muscles are brought into action to produce even a relatively simple eye movement.

The length of the two ascending MLF systems is important in consideration of the physiology of this reflex. Obviously the contralateral ascending system from the descending branch of the primary vestibular neuron has a significantly longer path than the ipsilateral ascending system. This alone could produce a significant delay in the neuronal impulse traveling over this pathway as compared to the same impulse carried ipsilaterally to the III and IV nuclei This delay could prevent antagonistic action and allow for a directional eye movement.

Finally there is also the possibility that one of these two ascending pathways may be inhib-

MACULAE

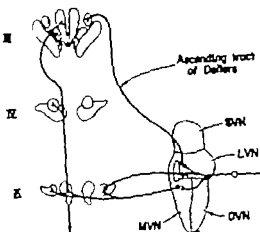

Fig. 59 Diagram summarizing the ascending pathways that may be activated by first order neurons from the maculae of utricle or saccule.

itory while the other is facilitatory allowing for a unidirectional eye movement.

In the second diagram (Fig. 59) a summary of the fibers from the otolithic sense organs, (utricle and saccule) could be represented by a fiber which has an ascending branch terminating in the ventral division of the lateral vestibular nucleus and a descending one terminating in the rostral portion of the medial estibular nucleus. Compensatory eye movements whether they be horizontal or vertical from utricular stimulation or the theoretical vertical movements from saccular stimulation could be carried out by the systems in this diagram. For example, stimulation of the lateral rectus and medial rectus muscles via the direct connections of the medial and lateral vestibular nuclei to the abducens (VI) and to the medial rectus (III) via the ascending contralateral system is evident. Movements of the inferior rectus by way of the ascending tract of Deiters and the superior rectus by way of the contralateral MLF system from the medial vestibular nucleus could be the pathway for vertical eye movements from stimulation of the saccule or vertical portion of the utricle.

C. DIRECT CEREBELLAR CONNECTIONS TO THE EYE NUCLEI

The interesting and unique direct cerebellar projection to the trochlear (IV) nucleus and oculomotor (III) complex that was demonstrated in the control group confirmed the previous finding of Carpenter & Strominger (1964) and others (Allen, 1924 Van Gehuchten, 1905 Gerebtzoff 1936, 1941 Klimoff 1898, 1899 Rasmussen, 1932). A clear demonstration of fibers of cerebellar origin coursing through the brachium conjunctivum was found terminating in the contralateral cells of the medial cell column of the oculomotor (III) complex and in a small portion of the contralateral trochlear (IV) nucleus. These innervate the ipsilateral superior rectus and superior oblique muscles respectively. Fibers reached these nuclear groups by passing in a dorsal direction from the region of the contralateral Red Nucleus and filtering at right angles through the longitudinally running fibers of the MLF

The functional significance of this fiber connection is not clear but, as it is a unique connection it is interesting to speculate on its significance. For example the tremendous number of cerebellar fibers terminating in the superior rectus muscle group may be responsible for strong inhibition of this group and perhaps making movements in this direction less apparent upon peripheral stimulation, such as from stimulation of the saccule.

D. PROJECTIONS TO RETICULAR FORMATION

The various lesions in this group of animals consistently produced significant degeneration to the ipsilateral reticular formation. In most cases precise terminal and preterminal degeneration patterns around the larger neurons could be found (Fig. 60). This connection points up the well-known relationship between the vestibular system and the reticular

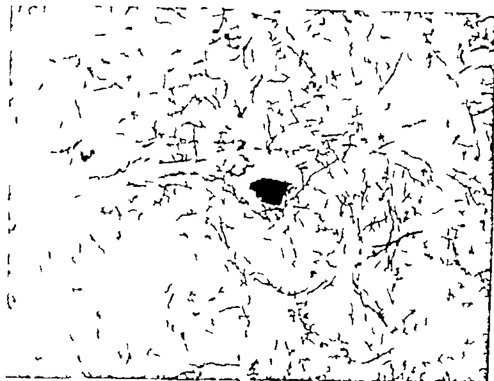

Fig 60 High power photomicrograph of a large neuron in the ipsilateral reticular formation in Cat 89 The degenerating terminals on the cell body and dendrites is typical of the lesions involving the vestibular nuclei in this study

formation and that patterned eye movements may be carried through the reticular formation.

However in this study as in any experiment where lesions are made in the vestibular nuclei interruption of cerebellar fibers (especially from the fastigial nucleus) as they pass through the vestibular nuclei to the reticular formation makes accurate interpretation difficult.

E. DESCENDING CONNECTIONS OF THE VESTIBULAR NUCLEI

Although this study concerned the ascending connections of the vestibular nuclei during the course of some lesions particularly in the caudal areas of the complex, descending fiber systems were interrupted. The diagram in Fig 61 summarizes the vestibular nuclei involved in the present experiment that also give rise to descending projections to spinal cord levels. General statements can be made at this time that the superior vestibular nucleus does not contribute to descending pathways to the cervical and lower cord regions. This contradicts the report by Buchanan (1937) in which it was stated that the superior vestibular nucleus does contribute to the lateral vestibulo-spinal tract. Lesions in the lateral vestibular nucleus consistently produced degenerating axons in the lateral vestibulo-spinal tract and only lesions in this nucleus produced degeneration in this tract this agreed with the studies of Brodal (1957 1962) and others (Buchanan 1937 Carpenter 1966) Lesions in the medial vestibular nucleus as indicated in the experimental animals, besides producing the ascending connections in the contralateral MLF also produced descending degenerating fibers in the medial portion of the contralateral MLF In many cases these apparently represent bifurcation of the fibers from the medial vestibular nucleus. Lesions in the descending vestibular nucleus were found to produce only descending connections by way of both the contralateral and ipsilateral descending MLF This group of fiber projections in a descending direction will be studied in more detail in another experiment.

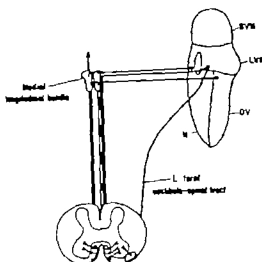

Fig. 61 Diagram summarizing the descending projections from the vestibular nuclei as determined from lesions in this study

F. VALUE OF SMALL NON-ELECTROLYTIC LESIONS

The importance of the smallest possible lesion in a complex area such as the vestibular nuclei for the evaluation of axonal degeneration was emphasized in this study. A non-electrolytic method using only a small straight probe produced such small lesions in the brainstem that the origin of the various fiber tracts could be determined.

The use of electric current usually produces relatively large lesions and always raises the question of current spread beyond the visible area of necrosis. Such large lesions make interpretation of degeneration patterns difficult and are probably responsible for conflicting results of other investigators in this area. Taking the superior vestibular nucleus as an example of how a large lesion can produce misleading degeneration patterns by injuring adjacent structures, the reports of Szentagothai (1964) and of Carpenter (1966) may be discussed. Knowledge of the direct cerebello-ocular fiber projection through the brachium conjunctivum to the superior rectus subgroup of the oculomotor (III) nucleus and to the contralateral trochlear (IV) nucleus is most important for proper evaluation of lesions in the superior vestibular nucleus. This was demonstrated in several animals in the present study. Interruption of this pathway by a large lesion of the SVN that also injures the adjacent brachium conjunctivum, is the most likely explanation for the findings of Szentagothai. He found degeneration primarily in the contralateral medial cell group (superior rectus) of III along with some degeneration to the ventral-lateral group of ipsilateral III (medial rectus) following a large lesion of the superior nucleus which unmistakably also involved the brachium conjunctivum. The conclusions drawn were that these represented the projection of the superior and horizontal semi-circular canals respectively.

In Carpenter's study degeneration in the oculomotor complex from superior vestibular nucleus lesions included the dorsal-lateral cell group which innervates the inferior rectus muscle. In the animals of the present study small lesions in all parts of the SVN conspicuously failed to produce degeneration in this part of the oculomotor complex. However, the ascending tract of Deiters, which is the only tract that terminates in this dorso-lateral cell group, does travel just ventral to the SVN as it ascends in the brainstem. The logical explanation for the discrepancy in results is that the relatively large electrolytic lesions in Carpenter's animals probably also injured the ascending tract of Deiters either directly or by spread of current beyond the confines of the superior vestibular nucleus.

G. NUCLEUS OF DARKSCHEWITSCH AND INTERSTITIAL NUCLEUS OF CAJAL

These two nuclei (Ingram, 1935) which lie just rostral to the oculomotor complex have been reported in several of the anatomical studies reviewed earlier to be the rostral termination of the ascending vestibular nuclear projections. This connection from both the ascend-

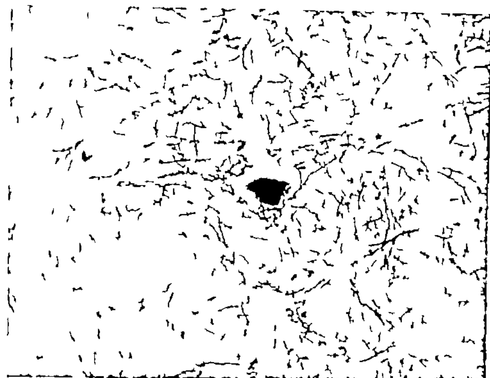

Fig 60 High power photomicrograph of a large neuron in the ipsilateral *reticular formation in Cat* 89 The degenerating terminals on the cell body and dendrites is typical of the lesions involving the vestibular nuclei *in this* study

formation and that patterned eye movements may be carried through the reticular formation

However in this study as in any experiment where lesions are made in the vestibular nuclei interruption of cerebellar fibers (especially from the *fastigial* nucleus) as they pass through the vestibular nuclei to the reticular formation makes accurate interpretation difficult

E. DESCENDING CONNECTIONS OF THE VESTIBULAR NUCLEI

Although this study concerned the *ascending* connections of the vestibular nuclei during the course of some lesions particularly in the caudal areas of the complex, descending fiber systems were interrupted. The diagram in Fig *61 summarizes the* vestibular *nuclei* involved in the present experiment that also give rise to descending projections to spinal cord levels. General statements can be made at this time that the *superior* vestibular *nucleus does not* contribute to descending pathways to the cervical and lower cord regions. This contradicts the report by Buchanan (1937) *in which it* was stated that the superior vestibular nucleus does contribute to the lateral vestibulo-spinal tract. Lesions in the lateral vestibular nucleus consistently produced degenerating axons in the lateral vestibulo-spinal tract and only lesions in this nucleus produced degeneration in this tract this agreed with the studies of Brodal (1957 1962) and others (Buchanan 1937 Carpenter 1966) Lesions in the medial vestibular nucleus as indicated in the experimental animals, besides producing the ascending connections in the contralateral MLF also produced descending degenerating fibers in the *medial portion of the contralateral* MLF In many cases these apparently represent bifurcation of the fibers from the medial vestibular nucleus. Lesions in the descending vestibular nucleus were *found to produce only descending* connections by way of both the contralateral and ipsilateral descending MLF This group of fiber projections in a descending direction *will be studied in more detail in* another experiment.

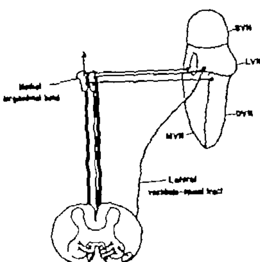

Fig 61 Diagram summarizing the descending projections from the vestibular nuclei as determined from lesions in this study

F VALUE OF SMALL NON ELECTROLYTIC LESIONS

The importance of the smallest possible lesion in a complex area such as the vestibular nuclei for the evaluation of axonal degeneration was emphasized in this study A non-electrolytic method using only a small straight probe produced such small lesions in the brainstem that the origin of the 'arious fiber tracts could be determined.

The use of electric current usually produces relatively large lesions and always raises the question of current spread beyond the visible area of necrosis. Such large lesions make interpretation of degeneration patterns difficult and are probably responsible for conflicting results of other investigators in this area. Taking the superior estibular nucleus as an example of how a large lesion can produce misleading degeneration patterns by injuring adjacent structures, the reports of Szentagothai (1964) and of Carpenter (1966) may be discussed. Knowledge of the direct cerebello-ocular fiber projection through the brachium conjunctivum to the superior rectus subgroup of the oculomotor (III) nucleus and to the contralateral trochlear (IV) nucleus is most important for proper evaluation of lesions in the superior vestibular nucleus. This was demonstrated in several animals in the present study Interruption of this pathway by a large lesion of the SVN that also injures the adjacent brachium conjunctivum, is the most likely explanation for the findings of Szentagothai. He found degeneration primarily in the contralateral medial cell group (superior rectus) of III along with some degeneration to the ventral-lateral group of ipsilateral III (medial rectus) following a large lesion of the superior nucleus which unmistakably also involved the brachium conjunctivum. The conclusions drawn were that these represented the projection of the superior and horizontal semi-circular canals respectively

In Carpenter s study degeneration in the oculomotor complex from superior vestibular nucleus lesions included the dorsal-lateral cell group which innervates the inferior rectus muscle. In the animals of the present study small lesions in all parts of the SVN conspicuosly failed to produce degeneration in this part of the oculomotor complex. However the ascending tract of Deiters, which is the only tract that terminates in this dorso-lateral cell group does travel just ventral to the SVN as it ascends in the brainstem. The logical explanation for the discrepancy in results is that the relatively large electrolytic lesions in Carpenter's animals probably also injured the ascending tract of Deiters either directly or by spread of current beyond the confines of the superior vestibular nucleus.

G NUCLEUS OF DARKSCHEWITSCH AND INTERSTITIAL NUCLEUS OF CAJAL

These two nuclei (Ingram, 1935) which lie just rostral to the oculomotor complex have been reported in several of the anatomical studies reviewed earlier to be the rostral termination of the ascending vestibular nuclear projections. This connection from both the ascend-

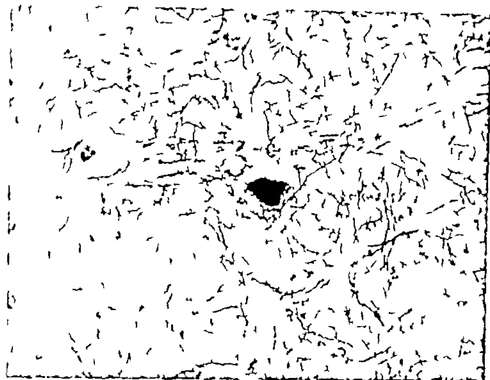

Fig 60 High power photomicrograph of a large neuron in the ipsilateral reticular formation in Cat 89 The degenerating terminals on the cell body and dendrites is typical of the lesions involving the vestibular nuclei in this study

formation and that patterned eye movements may be carried through the reticular formation

However in this study as in any experiment where lesions are made in the vestibular nuclei interruption of cerebellar fibers (especially from the fastigial nucleus) as they pass through the vestibular nuclei to the reticular formation makes accurate interpretation difficult.

E. DESCENDING CONNECTIONS OF THE VESTIBULAR NUCLEI

Although this study concerned the ascending connections of the vestibular nuclei during the course of some lesions particularly in the caudal areas of the complex, descending fiber systems were interrupted. The diagram in Fig 61 summarizes the vestibular nuclei involved in the present experiment that also give rise to descending projections to spinal cord levels. General statements can be made at this time that the superior vestibular nucleus does not contribute to descending pathways to the cervical and lower cord regions. This contradicts the report by Buchanan (1937) in which it was stated that the superior vestibular nucleus does contribute to the lateral vestibulo-spinal tract. Lesions in the lateral vestibular nucleus consistently produced degenerating axons in the lateral vestibulo-spinal tract and only lesions in this nucleus produced degeneration in this tract this agreed with the studies of Brodal (1957 1962) and others (Buchanan, 1937 Carpenter 1966) Lesions in the medial vestibular nucleus as indicated in the experimental animals, besides producing the ascending connections in the contralateral MLF also produced descending degenerating fibers in the medial portion of the contralateral MLF In many cases these apparently represent bifurcation of the fibers from the medial vestibular nucleus. Lesions in the descending vestibular nucleus were found to produce only descending connections by way of both the contralateral and ipsilateral descending MLF This group of fiber *projections in a descending direction will be studied in more detail in another experiment*

Summary

Utilizing the Nauta silver method to impregnate axonal degeneration 6 to 7 days following small non-electrolytic lesions in the vestibular nuclei of the cat, ascending projections to the extra ocular nuclei were demonstrated. Reconstructions of the lesion and degeneration pattern to the III IV and VI nuclei in twenty-four cats were carried out:

Three ascending systems from the vestibular nucleiar complex were shown.

1 An ipsilateral projection which originates in the superior vestibular nucleus, travels in the lateral half of the MLF and terminates in the ipsilateral IV nucleus, bilaterally in all except the dorso-lateral group of the oculomotor complex, and finally in the nucleus of Darkschewitsch and interstitial nucleus of Cajal of the ipsilateral side. No connections with the VI nucleus are made from this system.

2. A contralateral projection which originates primarily in the medial vestibular nucleus, ascends in the medial half of the contralateral MLF and terminates in the IV III nuclei and the nuclei of Darkschewitsch and Cajal in a manner similar to the ipsilateral system. However connections to both abducens (VI) nuclei are formed by this pathway with the ipsilateral nucleus receiving a more prominent one than the contralateral. Some of the connections with the abducens nucleus are also given by the ventral portion of the lateral vestibular nucleus.

3. An ipsilateral system that travels lateral to the MLF and originates from the ventral portion of the lateral vestibular nucleus. This tract has been called the ascending tract of Deiters" and its terminus was shown to be the dorso-lateral cell group of the ipsilateral oculomotor complex. This area innervates the inferior rectus muscle.

Demonstrated also was the presence of direct cerebellar fibers coursing in the brachium conjunctivum and terminating in the contralateral trochlear (IV) and the medial cell group of oculomotor (III) nucleus. The eye muscles influenced directly by this system are, therefore, the ipsilateral superior oblique and superior rectus respectively

Descending projections in the MLF to the spinal cord from the medial, descending and lateral vestibular nuclei as well as the vestibulo-spinal projection from the lateral vestibular nucleus were also confirmed by lesions and degeneration patterns in these animals.

ing systems of the MLF was confirmed in the present study The further projections of these two nuclei are not known.

Brodal (1957 1960) on the basis of retrograde cell change in the interstitial nucleus of Cajal following transection of the MLF in the medulla, has suggested that at least some of the cells in the I C. projected in a descending direction through the MLF There was some indication that one terminus of these fibers was the medial vestibular nucleus. The interstitial nucleus of Cajal, therefore *may represent a feed back center to the vestibular nuclei.*

Virtually no information on the connections of the nucleus of Darkschewitsch is available. Information on the course and termination of these two nuclei must be gained from axonal degeneration studies following lesions in the midbrain involving these nuclei. Such lesions will be difficult to produce in this very inaccessible area into which other nuclei and fiber tracts are also crowded. These studies are planned in the near future.

It is possible that these two nuclei may represent the further projection of the central vestibular pathway to the cortical level. Despite electrophysiological demonstrations of a *cortical vestibular area (Anderson 1954 Mussopust* 1960 Walzl, 1949) anatomical evidence of this part of the pathway has never been presented

A Theory and Physical Model for Cochlear Mechanics

BY

JOHN L. STEWART

From Santa Rita Technology Inc.,
Los Altos, California, USA

UPPSALA 1972

Introduction

Although basic to studies in psychoacoustics, there exists considerable misinformation on the mechanical properties of the cochlea, and data for use by investigators in devising instrumentation which behaves as does the ear are not readily available. Substantially different analyses for cochlear mechanics have too often only succeeded in perpetuating confusion as to the principles on which a model is based and just what a model can and can not do. This discussion is meant to provide clarification in four ways:

(1) A historical review of efforts at analyzing the cochlea is given in order to place the present work in proper perspective.

(2) Concepts of models for systems using electric circuits are discussed along with matters of relative accuracy and validity. It is shown how the final model results from a multi-step simplification of a complex three-dimensional lattice network. This section of the paper is partly tutorial.

(3) A specific numerical parameter set for an analog cochlea is provided which is suitable for extension and/or modification using conventional digital computer (time-share) techniques. The performance of the specific numerical model is shown with digitally computed characteristic patterns, impedances, and traveling waves. All curves given here are computed in this way. An appendix describes the computer program. An actual analog model has properties that are very close to these computed ones (within a few percent).

(4) The general nature of cochlear analysis is set forth using idealized functional representations. This part of the discussion is of basic importance in that it purports to deduce the basic rules for signal processing accomplished in the animal cochlea. This substantially nonspectral processing technique may also be accomplished in a multiplicity of neural structures central from the ear and also in nonauditory neural mechanisms. Cochlea-like analysis may have general applicability as an alternative to, or augmenter of Fourier methods.

A Short History

A number of analyses of the vibrations of the cochlea have been made in the past several decades and a few analog models have been constructed. Virtually all modern work in this area uses data deriving from the physiological studies of human preparations made by von Békésy (1960).

The earliest reasonably extensive effort to solve the problem of the cochlea dates from 1930 (where we ignore very early speculations based on a multiplicity of independent resonators). Theoretical formulations became more specific in the 1940's, with the work of Zwislocki (1948, 1949) and Ranke (1942, 1950) being singled out in particular. The works of Peterson & Bogert (1950), Bogert (1951), and

Elementary Functional Representations

When pictured as if rolled out into a straight line, the human cochlea appears as a tapered, fluid-filled tube which is separated into two channels with a structure having properties of mass and elasticity. This cochlear duct, containing the sensory cells, is bounded on one side with an elastic basilar membrane. The entire two-channel system is contained within presumably rigid walls. At the basal end it is closed except for two membrane-covered openings which provide access to the two channels. The stimulus is applied mechanically to one of these windows (the oval window). At the apex, the two channels inter-connect through a hole called the helicotrema.

In response to sinusoidal mechanical stimulation at the oval window fluids transmit pressure and particle velocity waves which move axially along the cochlear duct until a region is reached where duct mass and elasticity resonate so as to permit transverse motions between the two channels. The cochlea is said to localize the stimulus frequency in this region. The cochlea acts in the manner of a particular kind of hydrodynamic waveguide in which waves travel until reaching a cutoff region beyond which wave attenuation with distance is rapid.

The simplest concept of the cochlea assumes that fluids are constrained to move in only two directions, either axially along the cochlear duct or transversely to it. Equations of motion which countenance propagation as a sequence of events, increment by increment, can be formulated using this model. A general set of these is of second order for both fluid flow directions. That is, each has a first order differential, a first order integral, and a constant. When confined to linear systems, this assumption defines the (unbalanced) analog electric network structure of Fig. 1 (or its dual) wherein voltage and current represent pressure and fluid velocity respectively.

The network of Fig. 1 has been derived without considering any of the details of the cochlea itself. With use of one rather generalized boundary condition, an important modification results. Consider application of a constant pressure difference to the input with basal end windows being interpreted as simple holes. It is obvious from simple physical considerations that a steady fluid flow into one basal end window and out of the other will result. This means that none of the series string capacitors in Fig. 1 belong to the circuit representation if windows are ignored. But the membranous and elastic basal end windows prevent constant fluid flow in response to a pressure difference applied outside the windows. Representing this requires use of at least one series capacitor. Fig. 2 is for the modified network. This particular structure is the one generally used in representing the cochlea. The element values taper smoothly *from one end to* the other. An augmented basal end inductance accounts for comparatively large cochlear fluid volume (mass) near the windows, and the helicotrema resistance specifies hole size. The model does not allow for leaks between the two channels.

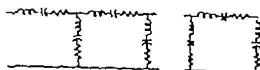

Fig. 1. General model for pair of second order difference equations representing law of physical activity

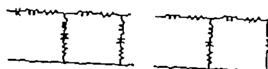

Fig. 2. General model allowing for continuous activity at arbitrarily low change rates except for one blocking element.

Fletcher (1951) appeared next Fletcher's early work (1930) is mentioned (but not in much detail) in his later book (1953)

In a 1953 historical survey Zwislocki (1953) observes that most theories differ not as to equations but rather as to particular parameter values, with those proposed by Fletcher (1951) being in best agreement with von Békésy's observations Certain analyses leading towards closed form solutions have necessitated use of approximations Zwislocki (1950) at one point ignores mass of the cochlear duct and Peterson & Bogert (1950) do not include dissipation Without damping a model will display wave *reflections* and act more like a cavity *than a* waveguide Fletcher (1951) points out the importance of dissipation in some detail

Studies subsequent to the foregoing which interpret system partial differential equations *of motion* for the cochlea provide little that is basically new These include our own earlier interpretation the main point of departure being that we used cochlear duct mass to infer elasticity *and* damping instead of relaying on von Békésy's hairprobe measurements We thus obtained a different set of parameters than found by other investigators (Caldwell et al 1962 Glaesser et al., 1963)

Several electric circuit analog models for the cochlea have been constructed based on data given in previously cited references The efforts of Bogert (1951) Bauch (1956) Wonsdronk (1961) and ourselves are cited In later versions of our own model, we abandoned the partial differential equation approach in favor of a topological one (Stewart 1967) This procedure does not constitute a denial of the validity of the differential equations rather it serves mainly to demonstrate the limitations of a simplified mathematical approach.

An analog ear structure of a different kind has been proposed by Flanagan (1960) He uses a delay line onto which are attached unsymmetric *bandpass filter* functions. He obtains *patterns* like those observed by von Békésy Flanagan's ear is a functional representation rather than a direct stimulation The individual bandpass filters do not separately distinguish effects *of outer and middle* parts of the ear from those due to the cochlea. The attenuation slopes of his filters above center frequency *may be too small*, although this particular restriction could be lifted with more complex bandpass functions. In general a *functional* model is not so capable of extension and *generalization* as is a direct stimulation (e g., in the representation of cochlear nonlinearities)

The problem of understanding cochlear mechanics has been approached by a *number* of investigators whose works are not so well known as those listed in the foregoing. For example Sakai & Ogushi (1968) provide a fairly detailed treatment. Studies are also given by Klatt (1964) Warnock (1964) Vallese (1964) and Klatt & Peterson (1966)

In addition to electric analog simulations, various attempts at building direct hydrodynamic models have been made commencing with razor blade glass-slide models described by von Békésy Such models are valuable for verifying and checking on physiological data, and can also aid in interpolation in cases where physiological data are difficult to acquire From a theoretical point of view however the scaled model is no more interpretable than is the cochlea itself and hence does not readily lead to a straightforward theoretical formulation for signal processing Even though the complete equations for the analog model may not be specified formally the very fact that the analog measures are quantitatively relatable provides a foundation of sufficient rigor for the needs of a satisfactory mathematical theory

Elementary Functional Representations

ben pictured as if rolled out into a straight ie, the human cochlea appears as a tapered, uid-filled tube which is separated into two hannels with a structure having properties of ass and elasticity. This cochlear duct, containing the sensory cells, is bounded on one ide with an elastic basilar membrane. The entire two-channel system is contained within presumably rigid walls. At the basal end it is closed except for two membrane-covered openings which provide access to the two channels. The stimulus is applied mechanically to one of these windows (the oval window). At the apex, the two channels inter-connect through a hole called the helicotrema.

In response to sinusoidal mechanical stimulation at the oval window fluids transmit pressure and particle velocity waves which move axially along the cochlear duct until a region is reached where duct mass and elasticity resonate so as to permit transverse motions between the two channels. The cochlea *is said to localize the stimulus frequency in this region.* The cochlea acts in the manner of a particular kind of hydrodynamic waveguide in which waves travel until reaching a cutoff region beyond which wave attenuation with distance is rapid.

The simplest concept of the cochlea assumes that fluids are constrained to move in only two directions, either axially along the cochlear duct or transversely to it. Equations of motion which countenance propagation as a *sequence of events*, increment by increment, can be *formulated using this model.* A general set of these is of second order for both fluid flow directions. That is, each has a first order differential, a first order integral, and a constant. When confined to *linear systems*, this assumption *defines the (unbalanced) analog electric network structure of Fig. 1 (or its dual) wherein voltage* and current represent *pressure and fluid velocity* respectively.

The network of Fig. 1 has been derived without considering any of the details of the cochlea itself. With use of one rather generalized boundary condition, an important modification results. Consider application of a constant pressure difference to the input with basal end windows being interpreted as simple holes. It is obvious from simple physical considerations that a steady fluid flow into one basal end window and out of the other will result. This means that none of the series string capacitors in Fig. 1 belong to the circuit representation if windows are ignored. But the membranous and elastic basal end *windows prevent constant fluid flow in response to a pressure difference applied* outside the *windows. Representing this* requires use of at least one series capacitor. Fig. 2 is for the modified network. This particular structure is the one generally used *in representing* the cochlea. The element values taper smoothly from one end to the other. An augmented basal end inductance accounts for comparatively large cochlear fluid volume (mass) near the windows, and the helicotrema resistance specifies hole size. The model does not allow for leaks between the two channels

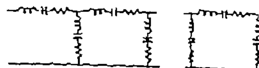

Fig. 1. General model for a pair of second order difference equations representing a line of physical activity.

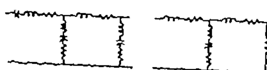

Fig. 2. General model allowing for continuous activity at arbitrarily low change rates except for one blocking element.

—this would require addition of certain elements such as resistor inductor circuits in parallel with the shunt resonant circuits

It is important to realize that the result has given almost no consideration to the details of the cochlea except for a rather broadly stated boundary condition The network can in fact represent a great variety of entirely different physical systems It is not really possible to closely identify network components in this model with parts of the cochlea For example, the shunt element resonant circuits may be only partly determined by the cochlear duct—for the influence of wall elasticity can also be represented here Series string elements may not directly represent channel fluid masses, but only a kind of equivalent mass, because particle velocities over the cross section of a channel may vary Response velocity may not be entirely represented by transverse current because this may also relate to wall rigidity and other factors and there will in any event be a location-dependent constant of proportionality relating this current to cochlear duct transverse response

Note on Approximation

The discrete lumped parameter network, or its ordinary differential equations which constitute an alternative description, comprises a more realistic model than does the set of partial differential equations for a continuous system The reason for this is simply that computations of a continuous system, whether by hand or with a computer must employ the difference equations which in fact relate to an equivalent lumped parameter system Furthermore even the development of the partial differential equation description is a limiting approximation of the discrete system The validity of the discrete representation for a system described with partial differential equations is in this sense beyond question But accuracy is another matter Accuracy depends upon the granularity of the increments, that is, the number of circuit elements used in the network Errors of representation depend upon the fractional difference between variables across a single increment or network section and this error can in principle be reduced without limit with a network of ever increasing complexity

A Note on Generalized Ladder Networks

The difference (or partial differential) equations leading to the structure of Fig. 1 comprise a rather general second order set. Thus the simple ladder network in Fig 1 has applicability to many modeling tasks However the ladder of Fig 1 is not a very general network Somewhat greater generality results upon replacing each separate resonant circuit with an arbitrarily complex impedance The only restriction on these impedance functions in order to guarantee physical realizability is that they be so-called positive-real functions.

A simple extension of Fig. 1 was briefly mentioned as a means for representing leaks through the cochlear duct But if the network shows elements representing these leaks or more general phenomena, then it could not come directly from the comparatively simple set of second-order difference equations. The description of continuous systems in science

seems most often to be in terms of fairly simple partial differential equations, and similarly for the corresponding difference equations. This would imply that many describable physical systems are either not really very complicated, or else partial differential equation representations as generally employed do not comprise very powerful tools. The procedure to be described next helps to demonstrate the power of semi-topological methods, a comparable derivation from the partial differential equations is not very tractable.

The Structural Model for a Rigid-Walled Pipe

An incompressable, nonturbulent fluid in a rigid-walled pipe behaves the same as a rigid mass insofar as overall input–output relationships are concerned. In particular for voltage and current the analogs of pressure and velocity respectively such a system can be represented as a single resistor in series with a single inductor. The inductor represents fluid mass and the resistor represents friction due to fluid viscosity the resistance value is zero for an ideal nonviscous fluid. If the incompressible fluid in the rigid-walled tube has input and output parts having different cross sectional areas, then the model additionally requires an ideal transformer to change the pressure to velocity (voltage to current) ratio

If flow over the cross section of a pipe is uniform and interest is in pressures and velocities at locations along the pipe, then a suitable model is a sequence of circuits in cascade each representing a small axial length. A pipe with changing cross section is represented as a sequence of simple resistance–inductance circuits interspersed with ideal transformers as in Fig. 3 The relationship of ideal transformer turns ratio to pipe cross section can be deduced from the principle of mass conservation The integral of fluid displacement, which is total fluid volume flow per unit time, must be constant.

Fig. 3 Representation for rigid-walled tube of varying cross section using ideal transformers.

Although useful for computational procedures, the model with ideal transformers is impractical in its literal analog form. A practical network requires removal of these transformers. In the case of circuits such as Fig. 3, this is possible using the device of impedance referral. That is, impedance elements can be moved from one side of an ideal transformer to the other as exemplified by the circuit in Fig. 4 A series of several ideal transformers can be removed by referring (somewhat tediously) across one section at a time until all such transformers are located at one end of the structure without intervening elements. Then all can be combined to a single ideal transformer The applied voltage is then simply scaled by the transformer and, since a simple scale factor is easily handled, even this one remaining transformer can be deleted. The final result is the simplified ladder in Fig. 5

If the fluid does not flow uniformly over the cross section of the pipe and if the state of fluids at points within the pipe is of interest, then a more detailed equivalent circuit must be employed. A small volume of incompressible fluid can be represented with partial differential equations and then subsequently modeled with a cubic array of resistor-inductor combinations. This representation has voltage and current as analogs for pressure and velocity respectively A large volume can be represented with many such circuits to give a space lattice where each lattice edge consists of a

—this would require addition of certain elements such as resistor inductor circuits in parallel with the shunt resonant circuits.

It is important to realize that the result has given almost no consideration to the details of the cochlea except for a rather broadly stated boundary condition The network can in fact represent a great variety of entirely different physical systems. It is not really possible to closely identify network components in this model with parts of the cochlea For example the shunt element resonant circuits may be only partly determined by the cochlear duct—for the influence of wall elasticity can also be represented here Series string elements may not directly represent channel fluid masses, but only a kind of equivalent mass, because particle velocities over the cross section of a channel may vary Response velocity may not be entirely represented by transverse current because this may also relate to wall rigidity and other factors and there will in any event be a location-dependent constant of proportionality relating this current to cochlear duct transverse response.

Note on Approximation

The discrete lumped parameter network or its ordinary differential equations which constitute an alternative description comprises a more realistic model than does the set of partial differential equations for a continuous system The reason for this is simply that computations of a continuous system whether by hand or with a computer must employ the difference equations which in fact relate to an equivalent lumped parameter system Furthermore even the development of the partial differential equation description is a limiting approximation of the discrete system

The validity of the discrete representation for a system described with partial differential equations is in this sense beyond question But accuracy is another matter Accuracy depends upon the granularity of the increments, that is, the number of circuit elements used in the network Errors of representation depend upon the fractional difference between variables across a single increment or network section, and this error can in principle be reduced without limit with a network of ever increasing complexity

A Note on Generalized Ladder Networks

The difference (or partial differential) equations leading to the structure of Fig. 1 comprise a rather general second order set Thus the simple ladder network in Fig 1 has applicability to many modeling tasks. However the ladder of Fig 1 is not a very general network. Somewhat greater generality results upon replacing each separate resonant circuit with an arbitrarily complex impedance The only restriction on these impedance functions in order to guarantee physical realizability is that they be so-called positive real functions.

A simple extension of Fig 1 was briefly mentioned as a means for representing leaks through the cochlear duct But if the network shows elements representing these leaks or more general phenomena, then it could not come directly from the comparatively simple set of second-order difference equations. The description of continuous systems in science

seems most often to be in terms of fairly simple partial differential equations, and similarly for the corresponding difference equations. This would imply that many describable physical systems are either not really very complicated, or else partial differential equation representations as generally employed do not comprise very powerful tools. The procedure to be described next helps to demonstrate the power of semi-topological methods, a comparable derivation from the partial differential equations is not very tractable.

The Structural Model for a Rigid-Walled Pipe

An incompressible, nonturbulent fluid in a rigid-walled pipe behaves the same as a rigid mass insofar as overall input-output relationships are concerned In particular for voltage and current the analogs of pressure and velocity respectively such a system can be represented as a single resistor in series with a single inductor The inductor represents fluid mass and the resistor represents friction due to fluid viscosity the resistance value is zero for an ideal nonviscous fluid. If the incompressible fluid in the rigid-walled tube has input and output parts having different cross sectional areas, then the model additionally requires an ideal transformer to change the pressure to velocity (voltage to current) ratio.

If flow over the cross section of a pipe is uniform and interest is in pressures and velocities at locations along the pipe, then a suitable model is a sequence of circuits in cascade, each representing a small axial length. A pipe with changing cross section is represented as a sequence of simple resistance–inductance circuits interspersed with ideal transformers as in Fig. 3 The relationship of ideal transformer turns ratio to pipe cross section can be deduced from the principle of mass conservation. The integral of fluid displacement, which is total fluid volume flow per unit time, must be constant.

Fig. 3. Representation for a rigid-walled tube of varying cross section using ideal transformers.

Although useful for computational procedures, the model with ideal transformers is impractical in its literal analog form. A practical network requires removal of these transformers. In the case of circuits such as Fig. 3, this is possible using the device of impedance referral. That is, impedance elements can be moved from one side of an ideal transformer to the other as exemplified by the circuit in Fig. 4 A series of several ideal transformers can be removed by referring (somewhat tediously) across one section at a time until all such transformers are located at one end of the structure without intervening elements. Then all can be combined to a single ideal transformer The applied voltage is then simply scaled by the transformer and, since a simple scale factor is easily handled, even this one remaining transformer can be deleted. The final result is the simplified ladder in Fig. 5

If the fluid does not flow uniformly over the cross section of the pipe and if the state of fluids at points within the pipe is of interest, then a more detailed equivalent circuit must be employed. A small volume of incompressible fluid can be represented with partial differential equations and then subsequently modeled with a cubic array of resistor-inductor combinations. This representation has voltage and current as analogs for pressure and velocity respectively A large volume can be represented with many such circuits to give a space lattice where each lattice edge consists of a

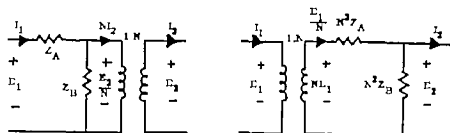

Fig 4 Referral of Impedances through an ideal transformer

series connection of one resistor and one in ductor A rigid boundary is represented as an open circuit for elements contiguous to this boundary A rigid walled tube of varying cross section is thus represented as a lattice of varying cross section and varying number of elements in each cross section. The elementary lattice element always represents a fixed volume A current injected at one end will flow with density inversely proportional to the number of elementary lattice units over the cross section and current magnitude in each series lattice element will similarly be inversely proportional to cross section Transverse elements contain currents only as needed to ac count for cross sectional changes To simplify this equivalent circuit to the form of a simple ladder is not quite so straightforward as in the case of uniform flow An equivalent aver age pressure and velocity over the cross sec tion of the pipe is implied by a simplified representation and shunt inductances are in troduced in order to represent transformer ac tion without transformers Each increment of length is thus represented as an el network of series R–L and shunt R–L. An ideal transformer with a 1 1 turns ratio can be identi fied with each series/shunt combination and combined in such a way as to change the turns ratio slightly and eliminate the shunt inductor This again results in a circuit as in Fig 3 which can subsequently be represented as in Fig 5 It follows that a rigid walled tube, uni form or tapered, carrying nonturbulent, in compressible fluids can be represented as a series of simple R–L combinations.

In order to be valid as a representation for increments along the tube the change in tube cross section per element of axial length must be small. This means that the step-up or step-down ratio of each transformer in Fig 3 must be small—for example 0 99 or 1 01 if errors are to be of the order of one percent It is also necessary that response variables represent only an overall average of fluid flow over the cross section of the tube because transverse currents are not accounted for in Fig 3

One of the restrictions on the foregoing model is that changes in cross section be gradual This implies that the pressure/velocity wavefront be substantially planar The re striction can be removed by separating the total fluid flow into stream tubes which individually have slowly varying cross sections. Each is treated as a separate rigid-walled struc ture It is helpful for present purposes to think of a rigid-walled tube starting and ending with

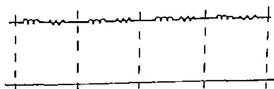

Fig 5 Representation for a rigid walled tube of varying cross section without use of ideal transformers. Element values taper according to variations in cross section. Position dependent scale factors must also be applied to voltage and current.

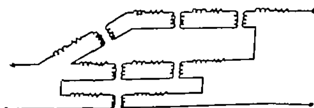

Fig 6 A hypothetical example of a representation for a three-channel system.

regions of slowly varying cross sections but which has intervening irregularities. Each streamtube will have the same number of sections (using the concept of conformal mapping) but numerical values for elements and transformer step-up or step-down ratios will vary. At the ends, all of the streamtube representations can be combined into a single one. Whether or not the system of ideal transformers can be eliminated by referral as before, the network remains a multi-path one as indicated in Fig. 6. Such a structure can not be described in simple terms with an elementary ladder network if details are to be retained. However if interest is confined to a sort of average system of pressures and velocities in the irregular region, the several pathways may be coalesced into a single one (providing the system does not involve separate distinct pathways).

Truly uniform fluid flow across a rigid-walled pipe is possible only for nonviscous liquids. This idealization does not constitute a good approximation except in some cases where cross sectional area is comparatively large. A streamtube approach is more appropriate for small pipes. But the final equivalent circuit can still imply an equivalent uniform flow and remain valid as to overall behavior.

The Problem of Nonrigid Walls

The resistance-inductance matrix representing a fluid region terminates in open circuits at rigid walls. For the case of non-rigid walls, terminations are impedance functions which can be simple or highly complex positive-real functions. With such terminations, transverse currents are important for structures with constant cross sections as well as for those with irregular ones. The separation of fluid flow into streamtubes is made extremely difficult because of the complex manner in which wall impedance functions can respond to pressure fluctuations. A yielding wall of any kind (if it is representative of a linear process) must always contain a measure of elasticity in its representation—which is capacitance in the circuit model. Necessity for capacitance is apparent if one considers what would happen otherwise: A constant pressure (voltage) to a resistor-inductor combination alone would result in constant velocity (current) flowing into the wall as long as the constant pressure was applied. It follows that, at very low frequencies, a wall will have the impedance of a capacitor and in the limit for a rigid wall the value for this capacitance goes to zero.

If a wall is very yielding, it has a circuit analog tending towards a short circuit—which contrasts with the open-circuit representation for a rigid wall. A tube with a yielding wall will not support flow that is uniform across the tube whether or not fluids are viscous. If the wall yields only when velocity fluctuations are within a restricted frequency range, then the wall capacitance must resonate with series-connected inductance; the equivalent mass of the wall provides the inductance parameter.

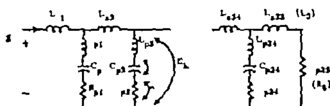
If a tube has a yielding wall on one side and a rigid wall on the other, the flow will tend to concentrate on the yielding side. If the tube has a large cross section, it may appear as if flowing waves are bound to the yielding part and remote fluids play almost no part in the process. The equivalent mass of moving fluids thus depends upon the nature of the boundary and in consort with wall elasticity the wave propagation velocity is also determined. (The equivalent of a yielding wall also describes behavior of so-called slow-wave propagation structures used in microwave circuits, and also certain kinds of electromagnetic and acoustic surface waves.) In hydrodynamic models of

the cochlea, von Békésy (1960) observed that cross section above a certain minimum value had little effect on motional patterns and activity was confined to a fluid layer adjacent to the elastic basilar membrane representation

A nonrigid wall becomes an array of resistor–inductor–capacitor circuits attached to points of the resistor–inductor space lattice representing fluids. The wall impedance elements can be highly complex and interconnected *within the wall itself* An especially complex situation arises when intrawall couplings are long range. A wave propagating along the tube at given velocity may be coupled via a re-entrant wall to establish itself ahead of or behind where it would occur if it traveled at normal velocity If this should prevail in a tube *which is intended to produce* space time patterns (like *the cochlea*) the formation of patterns would be inhibited An extreme example is given if walls of a closed tube (except for one end) move with the point of excitation—then nothing moves in the tube relative to its walls at all. (This is in part what occurs in the otosclerotic ear)

The Simplified Equivalent for the Cochlea

Two ducts are tapered, separated with a massive elastic structure and presumably have *rigid walls* Two suitably shaped space lattices *represent the two ducts. Walls are presumably* represented by open circuits but if these are not truly rigid, then more complex impedances for walls must be employed At least in approximation open circuits are assumed here



The cochlear duct is represented with an array of series resistor–inductor–capacitor circuits connecting appropriate points of the two space lattices together But since motion of a point on the cochlear duct will cause motion at adjacent points (because the duct is an integral structure) this array of duct connecting RLC circuits is in itself interconnected It is also complicated by variations in parameters between rigid edge attachments as well as by more gradual variations in the *axial direction*

To an approximation it would appear that intra-cochlear duct forces can be accounted for through suitable modifications of the edges of the fluid–representing resistor–inductor lattice which abuts the RLC cochlear duct representation Thus the structure appears the same as if no intra-cochlear duct forces exist but this is a fiction of equivalent circuits.

We now come to the task of reducing this rather complex three-dimensional circuit to a simple ladder as in Fig. 2 A gradual axial taper will require a series of ideal transformers. *Since the basilar membrane does not* have the same width as do the channels, a second set of transformers is needed to represent converging streamtubes in the transverse direction Clearly we must accept average velocities over the cross section and also an average one-dimensional RLC circuit array representation for the cochlear duct

After due manipulation, there results a balanced ladder network system having two sets of ideal transformers This structure can immediately be reduced to an unbalanced form Further (tedious) manipulations can work the two sets of transformers out of the system to give the network structure of Fig. 2 along with element values and necessary scale *factors relating voltages and currents* to fluid pressures and velocities, respectively

Inasmuch as there exist many uncertainties in the reduction process (as well as in parameters for the real cochlea) it is meaningless to retain very close numerical correspondence to such limited experimental data as are available. Rather a reasonable approximation that is not too difficult to express quantitatively is much to be preferred The approxima

tion is as follows. Except for terminating elements at basal and apical ends, all element values taper logarithmically from one end to the other. In particular, resonant frequencies of shunt circuits vary from 50 Hz at the apex to 20 000 Hz with Q values from 1.8 at the apex to 3.5. Inductance values in shunt circuits increase by a factor of 5 (logarithmically) from apical to basilar ends as do the series inductance values. Shunt inductors are larger than series inductors by a factor depending upon the total number of sections in the representation—the factor is 5 for 24 sections and 20 for 48 sections. Each series resistor inductor combination is such as to imply a Q value of 33.33 at 1 000 Hz. These several parameter value sets are regularized and smoothed versions of quantities estimated from physiological considerations (Stewart, 1967).

Computed Characteristics

An impedance and frequency normalized cochlea is useful for showing element values explicitly Fig 7 *a* shows the nomenclature for a 24 section cochlea (not including special basal elements) Fig 7 *b* is a table of element values, and Fig 7 c gives element value formulas.

The transverse velocity of the basilar membrane at a point along the basilar membrane is proportional to shunt circuit current, but *there exists a constant of proportionality that* depends upon index number K. Similarly transverse displacement is proportional to voltage across C_{pk} with an index-dependent constant of proportionality Initial studies of patterns can be made without considering these (frequency independent) constants.

A series of spatial patterns for various stimulus frequencies is shown in Figs. 8, 9 10, all relative to a normalized applied voltage of unity These (digitally computed) results are for total voltage across the shunt resonant circuits (cross-membrane pressure) total R_{pk} voltage (transverse velocity) and C_{pk} voltage (transverse displacement) The circles for the = 20 curve in Fig 8 are measured values for a physical analog network (SRT analog cochlear Model 2407P) Fig 11 is the input im

pedance magnitude and phase for the entire structure, also digitally computed. An appendix describes the computer program used in making these calculations.

Computer solutions can be made to yield both magnitude and phase. This permits data to be obtained for plotting a traveling wave. Fig. 12 is the pattern for a 20 radian sine wave (1 000 Hz *unnormalized*) at six different relative phase angles. The location for 20 Hz resonance is also indicated. (Note: For a fixed sine wave frequency displacement and velocity traveling wave patterns have identical shapes because one relates to the other as a constant, $j\omega$.)

Frequency characteristics for total R_{pk} and C_{pk} voltages are shown at several different locations in Figs. 13 and 14. These do not include index number constants of proportionality nor do they include frequency effects of outer and middle parts of the ear. These latter effects increase rates of attenuation for higher frequency parts of these curves (above 80 Hz, which corresponds to 4 kHz), and decrease cut-off rates at lower frequencies (below about 16 Hz, which corresponds to 800 Hz).

Estimated index-dependent constants of proportionality which apply to total R_{pk} and C_{pk}

voltages so as to yield transverse velocity and displacement, respectively are shown with dashed lines in Figs. 9 and 10. These curves are rather uncertain in the basal third of the cochlea. They have been estimated so as to yield the typical threshold characteristic (at cochlear pattern peaks) when a simplified representation for the transfer function of the outer and middle parts of the ear is employed.

Elasticity of the oval and round windows can be represented with a capacitor in series with L_{a} in Fig. 7 (7.5 E − 4 = 0.00075 fd). The attenuation across this capacitor is in the range 10–12 db per octave below about 16 Hz (800 Hz unnormalized). Except for transformer action this single element, as loaded by the cochlea, suffices to represent characteristics of outer and middle parts of the ear below about 40 Hz (2 000 Hz). Augmentation of L_{a} by a factor of several accounts for additional fluid masses near windows (from 0.133 to 0.39). With augmented L_{a} and the series capacitor a reasonable representation for outer and middle parts of the ear is given to frequencies at the upper end of the normal speech range. At higher frequencies, effects of ossicular mass and outer ear resonances cause further moderate changes to about 6 000 Hz, becoming increasingly marked as frequency increases beyond this.

General Discussion of the Model

The patterns provided by the specifically described analog model, and its input impedance, are in rather good agreement with von Békésy's (1960) observations. But patterns for frequencies above perhaps 40 Hz (2 KHz) are less certain. Recent measurements of a guinea pig cochlea suggest that Q values may become considerably larger at high frequencies (Johnstone et al., 1970). The present model allows for this to a certain extent by having Q values taper from 1.8 to 3.5. The generality of the equations permits an arbitrary taper rate and hence computer solutions could investigate what happens in this case. But with high Q values, a cochlea of only 24 sections may then not be adequate for representation near the basal end of the cochlea. Adequacy depends upon uses to which the analog model is to be put. If small differences between adjacent responses are of interest as, for example, in duplicating the tonal just-noticeable difference with these differences augmented by representations for neural inhibitory actions, then a very large number of sections is needed—enough to show discriminations of as little as 0.1 per cent in frequency. But if stimuli of interest are broadband signals such as speech up to perhaps 5 or 6 KHz (unnormalized), then the 24 section model should suffice. In terms of information content, it would appear that 24 sections is more than sufficient (Rink, 1970).

The analog model as discussed is a linear one. As such, turbulent fluid flow is not allowed; for a laminar flow model is needed in order to define streamtubes. It is believed by some that the cochlea vibrates with nonlinear motions to stimuli well within the normal range for speech perception. One concept is that of nonlinear fluid flow (Tonndorf 1960). The linear model then remains valid only if nonlinearities can be adequately represented with nonlinear components which are added to the linear system. Another concept has nonlinearities produced by asymmetric reaction of hair cells (Crane, 1966). This can be modeled with resistor-diode circuits placed across the C_{μ} elements so as to represent membrane displacement which is resisted more in one direction than in the other. Each such nonlinearity results in some envelope demodulation of lower frequency waves with these induced components then able to propagate along the cochlea, perhaps becoming augmented with contributions from other nonlinear circuits, as if the envelope component had existed in the applied stimulus. This type of nonlinearity is not of a simple "cubic" type. Rather the magnitude of the induced component is directly proportional to the magnitude of the stimulus.

This distributed nonlinearity representation may also provide a reasonable model for nonlinear fluid flow if this should in fact exist. The exact nature of the nonlinearities is actually not specified by the circuit representation.

A third concept for cochlear nonlinearity is that of asymmetric streaming of fluids in and around the oval window perhaps into the vestibular apparatus (von Békésy 1960). This concept can be modeled with a resistor-diode combination placed *after* the series *capacitor* representation for the oval window. It gives properties similar to those given with nonlinearities across the C_{μ} elements, but somewhat simpler in its effects on waveforms. The single diode-resistor combination has been used as a part of a model for the echoranging bat with some success (Stewart & Katson, 1969 Stewart, 1970). The distributed nonlinearity has been used in an attempt to explain *subjective* tones in human perception, also with some success (Stewart, 1970).

Cochlear nonlinearities could also be associated with nonrigid walls. To locate diodes with C_{μ} elements is thus somewhat mislead-

ing but not necessarily incorrect for in the simplified ladder network both the wall and the cochlear duct are accounted for with the same shunt circuit representation

Stimulation of the cochlea with bone conducted signals requires some re interpretation but not a change in the model itself At least for the linear model, the principles of reciprocity and superposition prevail In bone conduction elements of fluid throughout the cochlea are excited. But each elementary excitation can be referred to the input end by virtue of reciprocity then by virtue of the principle of superposition all of these incremental effects can be combined into a single equivalent stimulus at the oval window The difference between normal and bone conduction stimulation of a linear ear is thus explainable in terms of differences in the transfer functions between the source of sound and pressure on the oval window If the cochlea is nonlinear then neither reciprocity nor superposition apply except as approximations and to this extent bone conduction stimulation may not have an outer-ear equivalent.

The linear ladder network with general positive real functions for series and shunt arms, and whether balance or unbalanced is a so-called minimum phase network This means that given the magnitude transfer function from one series or shunt branch current or voltage to another then the imaginary part or real part or phase angle can be computed Or one can start with the phase function or the real part etc and compute all of the others. One technique for making trial computations manipulates the poles and zeros. Another employs the Hilbert transform (Bode, 1945) Applied to the present situation the minimum phase condition means that gain and phase and group delay (slope of the phase function) are entirely related. Thus a time-based interpretation is equivalent to a frequency based one and, unless concern is for waveforms more complex than sine waves, arguments supporting one interpretation over another are rather meaningless.

The rigid walled tube would appear to be representable with minimum-phase functions, even in its space lattice embodiment. A tube with yielding walls may or may not be so representable depending upon possible existence of reentrant pathways. Any structure having multiple paths between input and output such as a space lattice or paralleled ladder networks, may or may not be minimum-phase but a ladder network whose arms are positive real impedances is always minimum-phase. A distinctive nonminimum-phase structure could be one consisting of a yielding walled tube with a second one entering and leaving from different points in which wave travel times are significantly different over the two paths.

In a nonlinear structure most concepts relating to linear circuit analysis begin to break down This includes the concept of the minimum-phase property except of course, in approximation If nonlinearities create components but do not greatly change those already present or change induced components once these are in existence then the concept of minimum phase remains reasonably valid

Low Pass Filter Cascades

A study of the behavior of the cochlea with various idealizations leads to a fairly simple concept for method of analysis. That is, points along the basilar membrane respond to stimuli at the input to the system as a series of low pass filters whose cut-off frequencies are related by equal ratios (i.e., uniformly spaced on a log frequency scale) Fig 15 demonstrates these idealized transfer functions for a sequence of cochlear positions.

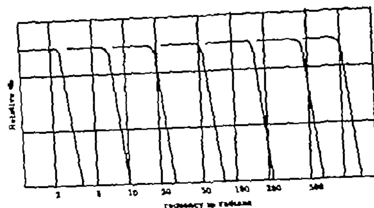

Fig. 15. A sequence of low pass functions as model for cochlear analysis. In this case, using the same normalization as previously capability beyond the normal human range is indicated by the use of filter function with cutoff frequency above 400 radius.

Response levels of the several low pass functions may not be the same. Amplitude weighting can be of two basic kinds, frequency-dependent and frequency-independent. A magnitude scale factor applied separately at each response location constitutes frequency-independent scaling. A common filter function which affects all response locations alike will vary in magnitude and phase with frequency and as such is frequency dependent. If the system of low pass functions is dependently scaled with a common multiplier $j\omega$ then an alternative point of view is that response becomes the time rate of change of what it was without the $j\omega$ factor. If the low pass function represents basilar membrane displacement, for example, then the representation with the $j\omega$ multiplier is of velocity.

A particularly interesting special case has the $j\omega$ factor and also an independent scale factor such that all peak responses are the same to give the filter system curves as in Fig. 16. If these curves are multiplied with a frequency-dependent bandpass function as shown dashed in Fig. 16, the overall system models the human ear. The dashed overall function represents the transfer characteristic of outer and middle parts of the ear including the oval-round window interface.

Cochlear localization patterns can be computed and plotted directly from the system of curves of Fig. 16. The idealized low pass system of Fig. 15 will also reveal localization provided that an independent scale factor is applied such that magnitude decreases with cut-off frequency (by about 50 db over the 1–400 Hz range, which corresponds to the normal range of 50–20 000 Hz).

The cut-off characteristics of the several low pass filters in Fig. 15 are not arbitrary. Ideally all curves are identical except for translation corresponding to frequency scaling. This assures that the phase characteristic from point to-point along the cochlea will be uniform and regular such that a wave will travel with gradually decreasing velocity until it disappears into an attenuating region. Since the cochlea models as a minimum phase function, this phase characteristic can be computed from the magnitude function of the low pass filter or conversely.

The most often accepted view of the cochlea is that of a frequency resolver. Indeed it does this to a certain extent, but it does not do it according to a classical filter band concept. In spectrum analysis, the phase function is usually ignored and it may not be under much control in any event. The way in which neural volleys are induced from a traveling wave along the basilar membrane can not readily be represented or even understood in terms of a classical frequency band concept. Rather gradual transitions from one position to the next become dominant factors in interpretation.

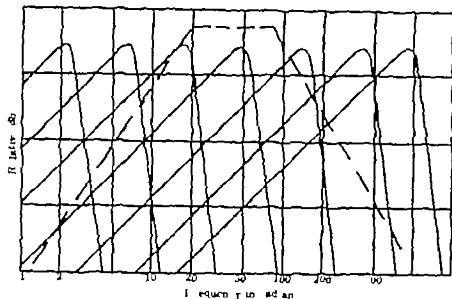

Fig 16 A sequence of overlapping bandpass functions as a model for cochlear analysis. *The multiplicative* outer-middle ear function is also shown (un-normalized corner frequencies being 1 000 Hz and 4 000 Hz).

Analysis of the cochlea in terms of low pass *bands is not a* generally accepted notion, al*though the traveling wave picture seems to be* becoming more common Innomata (1963) suggests *a low pass* band system. Peterson & Bogert (1950) and Fletcher (1951) might have discovered the low pass characterization from their pressure difference curves had they suitably accounted for complex arrangements of equivalent ideal transformers

Natural systems of many kinds support *traveling waves which may tend to disappear* after traveling a distance depending upon frequency Thermal and other diffusion processes behave in this way A diffusion of neural activity can also display this behavior and if this is combined with rate sensitivity a system of responses like those in Fig 16 but at a lower frequency could readily be mechanized In short, analysis of volleys of neural impulses in the central region can *take place* in analogy to analysis of sound volleys in the cochlea. Even a simple animal such as a small insect can have this capability The significance of cochlea like analysis has been recognized by a few investigators but much remains to be done (Lucas et al. 1966 Stewart, 1970 1971)

Summary

An electric circuit analog for basilar membrane vibrations is developed as a gradual *reduction of a complex three dimensional* hydrodynamic structure Specific circuits with element values are presented along with digital computer programs and numerical solutions. Information is sufficient to permit the reasonably competent designer/technician to construct his own circuit model Flexibility in design and generality of the theory allow for study of the effects of parameter changes by digital computer means The theoretical approach is meant to provide insight into both capabilities and limitations of the model and permit its extension and elaboration so as to represent additional phenomena The basic nature of the functional processing carried out by the cochlea is identified and described in terms of idealized response characteristics.

Appendix

DIGITAL COMPUTER PROGRAM

Element labeling is somewhat different from that previously described due to limitations in computer program designations. Analysis is of a rather general cascade of "L" network ladder sections. Fig. A 1 shows the general section where impedances are expressed in terms of real and imaginary parts, and Fig. A 2 shows the specific case of interest here. The individual L sections combine to form the complete network shown in Fig. A 3 (where differences in element nomenclature are to be noted).

The computer analyses begins by assuming a voltage across R0. The corresponding voltage and current relationships at the next section towards the input are computed and this procedure continues, section by section, until the input voltage and current are found. The magnitude of the input voltage is then used as a normalizing factor. The entire computation is repeated starting with the voltage across R0 which will result in an input voltage magnitude of unity.

The computer program is written in "Basic" language and the facility was a Hewlett Packard 2000A Time Share system. A telephone coupled terminal with a teletypewriter provided the input and output.

The program is shown in Fig. A 4 and the printout for the particular (normalized) frequency of 20 radius is shown in Fig. A 5. The computation of input impedance uses a simple self-evident modification of the program in Fig. A 4. To obtain data for the traveling wave, a different modification was done (not

shown here) in which the relative phase angle of the stimulus was also a parameter

Program statements, in major groups, are described as follows.

20 30	Input frequency typed in
50	Printout table headings.
70	Number of sections.
80	Nepers to decibels.
90 100	End section values.
110–120	First assumption on voltage at R0 An overflow can be handled by changing the value of E0
130	Element taper constants (can be anywhere in program)
140	Start with normalizing loop.
150–190	End section computations.
200	Start section stepping
230–300	Taper equations.
310–400	Compute for one L section.
410	Skip printing on normalizing loop.
420	Print data (this can be expanded in many ways)
430–500	Compute at next section towards input
510–540	Relable for next section
550	Section number loop
560 570	Adjust output volts for $1 + j0$ input.
580	Normalizing loop
610	Return for a new frequency

End section values can be changed over wide limits in 90 and 100 in order to answer such

Fig. A 5. Numerical printout sample for $\omega = 20$.

questions as the effect of the equivalent impedance for the helicotrema. Data in statement 130 can be changed to study effects of taper rates and relevant constants (see Read statement 220 for definitions of constants). The Q of the series elements is set in statement 290.

Print statement 420 can be modified in many ways, as can table headings, etc. For example, curves of several variables, in decibels, can be printed directly by the terminal as functions of section number using different teletypewriter symbols for the different curves. But these things constitute conveniences which are not important here.

Even though a comparatively inexpensive time sharing service was employed, apparent speed of computations is maximal. That is, central processor delay is less than the time required to type table headings. A representative computer connection cost for the data in Fig. A 5 is in the range 15 to 60 cents, depending on time of day, facility and other factors (or even less using Image statements so as to get more compact printout).

Introduction

The posterior colliculus is an imposing part of the auditory system in the midbrain tectum. It functions in the propagation of auditory signals to the medial geniculate body (Bechterew 1895), in the integration of the ascending and descending auditory pathways implicated in central auditory "feedback" adjustments (Rasmussen, 1964 Desmedt, 1960 Massopust & Ordy 1962), and in the elaboration of acoustic reflexes (Ades, 1944 Buser St. Laurent & Menini, 1966). All of the known auditory pathways undergo obligatory synaptic interruption at the level of the posterior colliculus (Lewandowsky 1904 Rasmussen, 1964 Morest, 1965 *b*). *It is important to comprehend the detailed structure of the posterior colliculus, since it subserves several different auditory functions* and since a *significant analysis of sound may already be achieved at this level* of the auditory system (Neff 1961). Moreover the tonotopic organization of the auditory nuclei (Rose, Galambos & Hughes, 1959 Rose, Greenwood, Goldberg & Hind, 1963 Tsuchitani & Boudreau, 1966 Guinan, 1968), which corresponds to the orderly arrangement of axons in these regions, including the medial geniculate body (Morest, 1965 *a*) and the posterior colliculus (Morest, 1964 *b*) of cats, implies an orderly arrangement of the neurons in the posterior colliculus of the human also.

Unfortunately the desired picture of the minute structure of the posterior colliculus is not provided by the available histological studies, which are often limited to the Nissl and Weigert methods (e.g., Winkler 1921 Riley 1943), with the provocative exception of a few precious observations with the Golgi method by Ramón y Cajal (1911) in the mouse, cat, and dog. Recently a detailed analysis of the neuronal architecture of the posterior colliculus has been pursued in the cat with the Golgi method and with experimental degeneration methods (Morest, 1964 *b* 1966 *a*, 1966 *b*). This work has demonstrated an orderly laminar arrangement of the axons and dendrites of the central nucleus of the posterior colliculus that may account for the tonotopic organization of the ascending auditory pathway in the midbrain. A cortical structure has also been characterized that could provide for the complex integration of the ascending and descending auditory pathways. Peri-collicular groups of neurons, some of which could integrate somatic sensory and auditory inputs, have also been identified.

The present investigation provides a detailed description of the neuronal architecture of the human posterior colliculus. This study should help to define the possible functional significance of the human posterior colliculus by facilitating references to the experimental analyses of the homologous structures in the cat.

Materials and Methods

The analysis was made on Golgi-Cox impregnations (Van der Loos, 1959) of fifteen human midbrains, ranging in age from 24 weeks of gestation to 74 years (see Table I). The fresh tissue was cut into slices 3–5 mm thick and immersed in the Golgi-Cox fixative,

usually less than four hours after death After celloidin embedding unbroken series of sections, 150 μ thick were made in one of the three standard planes frontal sagittal and horizontal The distribution of the neurons impregnated in each of these planes was reconstructed from serial sections on transparent plastic sheets with the aid of photomicrographs and a stereomicroscope with a drawing attachment. The drawings were made with a compound microscope having semi-apochromatic objectives and a drawing attachment. The observations were compared with preparations stained by the cresyl violet Klüver and Loyez methods,[1] and with Golgi-Cox impregnations of adult cat brains sectioned in the three standard planes. This report adheres to the conventions of comparative anatomy The rostral and caudal directions are designated as anterior and posterior respectively the back and front as dorsal and ventral. The findings exemplify the posterior colliculus in the mature brain unless otherwise indicated

Results

The three main divisions of the posterior colliculus are readily apparent in the Golgi preparations, as well as in the myelin and cell stained material the central nucleus, the cortex, and the peri-collicular tegmentum (Figs 1–7) The central nucleus (*CN*) is an ovoid mass of cells, occupying the core of the posterior colliculus The nucleus is separated from the surface of the collicular convexity by the cortex dorsally (*DC*) and caudally (*CC*) The peri-collicular tegmentum (*IT LZ C* respectively) separates the central nucleus from the anterior colliculus, from the lateral surface of the tectum and from the underlying regions of the midbrain tegmentum Most of the heavily myelinated tracts, running to and from the central nucleus, collect in the peri-collicular teg

mentum and in the superficial cortex, so that in myelin-stained sections the central nucleus seems to be encapsulated (Fig. 1). The brachium of the posterior colliculus, containing the axons ascending to the medial geniculate body and descending from the auditory cortex, appears in the lateral zone (*LZ*) of the colliculus, whereas the lateral lemniscus (*LL*), containing the ascending auditory axons to the central nucleus, gathers at the posteroventral pole of the *central nucleus*. The *commissure* of the posterior colliculus (*CX IC*) contains myelinated axons passing between the posterior colliculi over the cerebral aqueduct and central gray (*CG*) at the level of the trochlear nucleus.

The central nucleus consists of a mass of densely packed nerve cell bodies of many sizes and shapes (Figs. 7, 8, 11), intermingled as if at random. We have not attempted to delineate subdivisions of the central nucleus, as in the cat (Morest, 1966 *b*). However, in Golgi impregnations it is possible to distinguish several types of neurons on the basis of their dendritic morphology. These types are not intermingled haphazardly, but they are arranged in a specific order. This order is defined by the spatial orientation of the dendrites of the different types of neurons. There are at least five types of neurons, two of which have disc-shaped *dendritic fields* (*Figs. 8, 9, 10*) and three of which have stellate dendrites (Figs. 16, 17, 18).

The disc-shaped neurons line up with their

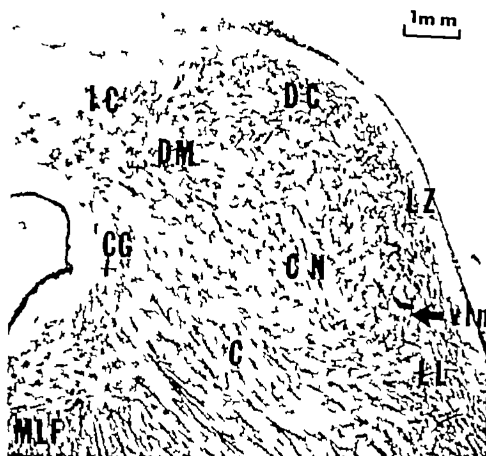

Fig 3 Frontal section at the junction of the caudal and middle thirds of the posterior colliculus of a 55 year old man Note lack of impregnation of the superficial zone or capsule of the colliculus, as is characteristic of the present series. Golgi-Cox method.

long axes in parallel, so as to form columns or rather layers of their dendrites (Fig. 11). Such layers establish a striated pattern in sections through the central nucleus, which can be accurately delineated by reference to the striae. The striation, or lamination pattern, has been reconstructed in its entirety with tracings from serial sections on transparent sheets (Figs. 11–14). The pattern is consistent in different specimens and in reconstructions from different planes of section. The layers of disc shaped dendrites seem to diverge from the posteroventral and lateral pole of the nucleus, then sweep in nearly parallel layers anteriorly and medially in an oblique, almost horizontal plane, to the anterodorsal and medial pole of the nucleus. As the dendritic layers sweep across the central nucleus in this way there is a gradual shift in the curvature of the individual layers and the disc-shaped dendritic fields forming them (Figs. 14, 15). The number of individual layers, or the number of neurons *forming a functional laminar unit,* is not *known,* since there is no obvious structural boundary between the layers. Indeed, the dendrites *of the individual* cells always overlap

The dorsal (dashed) leading edges of each disc rotate from a caudo-dorsal to a rostro-dorsal orientation along the caudo-medial to rostro-lateral axis of the nucleus. The inset diagram at the upper left shows the approximate site of the reconstructed area projected upon a diagram of the dorsal surface of the tectum.

Fig 14 Orientation of the dendritic laminae of the central nucleus (*5*) as seen in horizontal sections from a 24 week old fetus. In the right half of the figure the outlines from the right posterior colliculus appear at evenly spaced intervals in the central nucleus progressing from the ventral fourth at the top to the dorsal fourth at the bottom. In the left half of the figure are the outlines from the left posterior colliculus these correspond to more ventral levels than their partners because of the oblique plane of section *1* lateral edge of the right posterior colliculus, commissure of the posterior colliculus *3* axons of the lateral lemniscus, *4* caudo-central zone occupied by ascending lateral lemniscus *5* dendritic laminae of the central nucleus.

the latter it is more nearly vertical in orientation

The great majority of the disc shaped neurons appear equally divided between two main types, large and small (Fig 8) *The large disc shaped neuron* often has a dendritic field as long as one millimeter sometimes even longer (Fig 9) The dendrites are less elaborately branched than the other types in the central nucleus At the ventral, lateral and anterior boundaries of the nucleus, the dendrites often spread across the borders into the peri-collicular zones (Figs 19 *D* 28 *I* 30 *b*) but in the medial margin of the lateral zone their dendrites often bend to run in parallel with the boundary itself Dendritic growth cones evidence of late dendritic growth (Morest

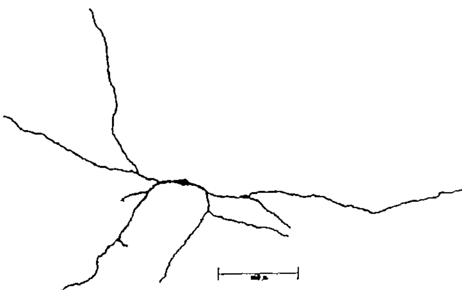

Fig. 16 Small stellate neuron, as seen in parasagittal section from the central nucleus of a 53 year old man. The dendrites in the long axis of the cell (from left to right) extend within the dendritic laminae in an antero-posterior direction. The dendrites projecting toward the lower left corner of the field extend in the horizontal plane within the dendritic laminae. The long dendritic branch pointing toward the top of the field transects the dendritic laminae in the dorso-ventral plane. Crosses at the tips of the processes in this and other figures indicate where they are transected at the surfaces of the sections.

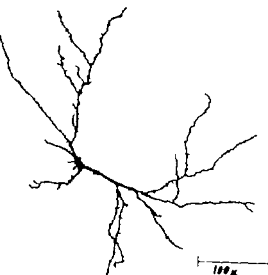

Fig. 17 Medium-sized stellate neuron, as seen in parasagittal section from the central nucleus of 53 year old man. The long axis of the dendritic field transects the plane of the dendritic laminae.

1969), appear commonly as they do on other cells in the posterior colliculus (Fig. 9). This occurs in adult as well as infant or fetal brains. The axon of the cell usually arises from the perikaryon. The initial direction of the axon varies and cannot be traced farther in these preparations. The long axis of this neuron is parallel to the incoming axons from the lateral lemniscus. *The small disc shaped neuron* has a dendritic field approximately 600 μ long (Fig. 10). It is mingled with large disc-shaped neurons, the dendrites of which branch in a similar pattern. However, the small cell has thinner dendrites with branches arranged in more or less discrete tufts. The usual course of their axons is uncertain, but in some cases, as the axons cross the laminae, they give off collaterals in nearby laminae (Fig. 10 *a*). This type of neuron is homologous to the small disc-shaped neurons described in the central nucleus of the posterior colliculus of the cat (Morest, 1964 *b*).

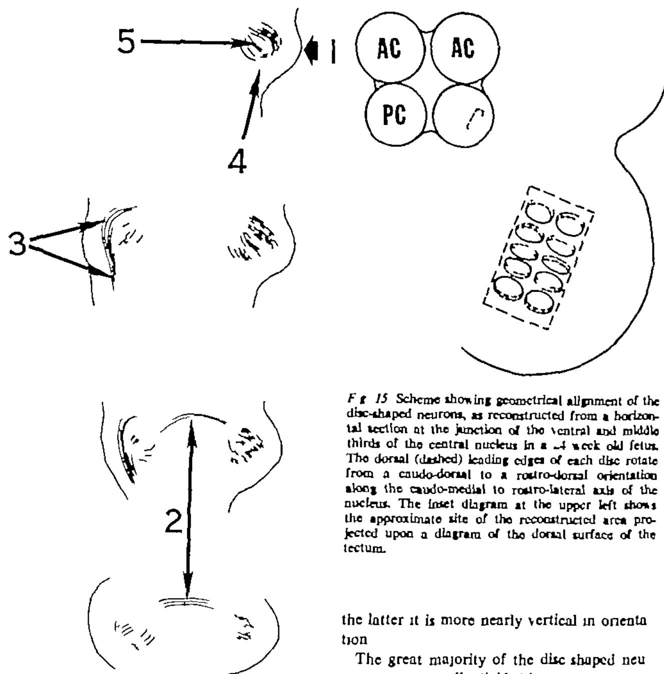

Fig 14 Orientation of the dendritic laminae of the central nucleus (*5*) as seen in horizontal sections from a 24 week old fetus. In the right half of the figure the outlines from the right posterior colliculus appear at evenly spaced intervals in the central nucleus, progressing from the ventral fourth at the top to the dorsal fourth at the bottom In the left half of the figure are the outlines from the left posterior colliculus, these correspond to more central levels than their partners because of the oblique plane of section. *1* lateral edge of the right posterior colliculus *2* commissure of the posterior colliculus, *3* axons of the lateral lemniscus, *4* caudo-ventral zone occupied by ascending lateral lemniscus, *5* dendritic laminae of the central nucleus.

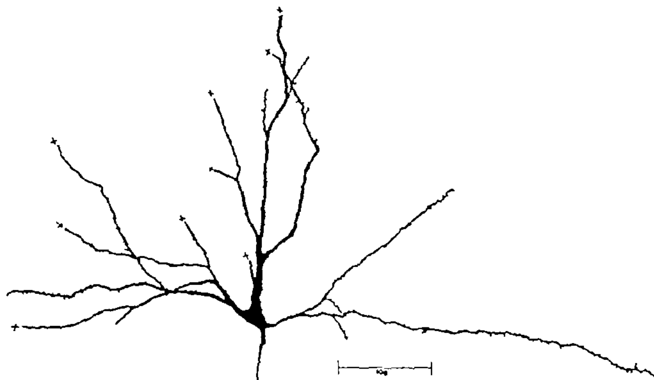

Fig 18 Large stellate neuron from a parasagittal section of the central nucleus of a 53 year old man. The dendrites cross the dendritic laminae at various angles. The thick initial segment of the axon projects from the perikaryon toward the bottom of the field.

The stellate cells appear to be less frequent than the disc shaped cells, although they appear throughout the central nucleus. At least three varieties of stellate cells can be distinguished small medium and large *The small stellate cell* is multipolar and has long thin dendrites, arranged in an elliptical field with a long axis of 600–800 μ (Fig. 16) The dendrites tend to collect in mutually perpendicular strands, either parallel or normal to the laminae The longest dendrites run parallel to the laminae and to the long axis of the disc shaped neurons Similar cells occur in the central nucleus of the cat's posterior colliculus (Morest, 1964 *b*) *The medium stellate cell* is a medium sized neuron, the dendrites of which radiate in a spheroidal field (Fig 17) The diameter of the dendritic field ranges from 600–800 μ its long axis crosses the dendritic laminae of the central nucleus at right angles. However some of the secondary branches may run parallel to the dendritic laminae Some dendritic branches may bend and travel with the incoming fibers of the central nucleus, while other branches may extend in various directions across or through the laminae Dendritic growth cones are evident *The large stellate cell* has dendrites, arranged in a spheroidal field, which cross the laminae in multiple directions (Fig 18) The diameter of the dendritic field usually approaches, and often exceeds, one millimeter This type of neuron appears to have a relatively low incidence. An analogous type of neuron has been observed in the central nucleus of the cat (Morest, 1964 *b*)

The cortex of the posterior colliculus contains different types and sizes of neurons, the bodies of which are situated in separate layers (Fig 7 DC) As in the cerebral cortex the dendrites of the neurons often cross more than one layer (Figs. 19 22) The cortex of the human posterior colliculus extends from the posterior end of the anterior colliculus and the dorsal tip of the intercollicular tegmentum over the dorsal convexity of the colliculus and onto the free posterior margin of the colliculus (the

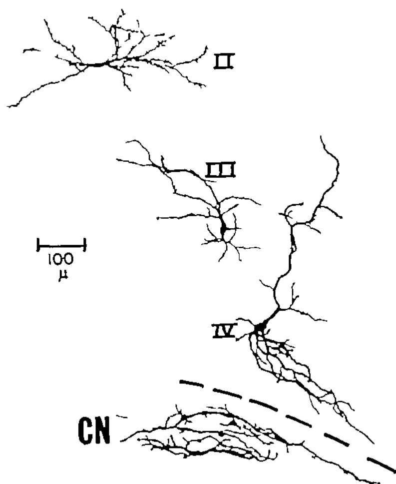

Fig 21 Dorsal cortex. Detail from Fig 19 showing the main cell types that distinguish layers II III and IV
A Initial segments of axons.

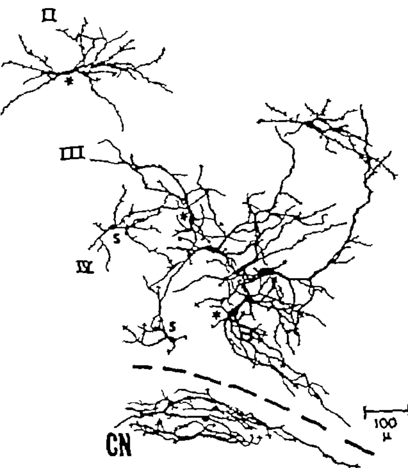

Fig. 22. Dorsal cortex. Same neurons ( ) as in preceding figure, but more examples are added to illustrate some of the overlap between different layers by the dendritic processes, and to show the small neurons ( ) that occur in both layers III and IV. *A*, a, initial segments of axons. The rostral direction is to the left.

caudal cortex) as far as the attachment of the anterior medullary velum and the decussation of the trochlear nerve (Figs. 4–6). Laterally the cortex gradually gives way to the lateral zone (Figs. 1–3, 7). In the human cortex, as in cats (Morest, 1966 *a*), four layers may be distinguished through most of its extent. However, in the caudal cortex and laterally the superficial layers attenuate greatly and eventually disappear posteroventrally. Also a fifth layer might be distinguished anteromedially in association with the fibers entering or leaving the commissure of the posterior colliculus (Figs. 7 *IC*, 19 *E*; see also Morest, 1966 *a*). In the present study we shall designate this last region, the intercollicular commissural zone. Generally in the cortex of the human posterior colliculus, as in the cat, larger neurons occur in successively deeper layers.

In layer I there are small neurons with radiating dendrites in flattened fields, oriented *parallel to the fiber capsule of the tectal convexity*. Because the impregnation of the margins of the present preparations is scanty, few neurons could be observed. Of course, their perikarya are readily demonstrable in Nissl-stained sections (Fig. 4). More centrally in *layer II* there is a small to medium-sized multipolar neuron (Figs. 19, 20). Its ovoid dendritic field, 600–800 μ in diameter, is aligned nearly parallel to the collicular surface (Figs. 21, 23). The axons leave the perikarya and take a course parallel to the convexity of the collicular surface. *Layer III* contains a medium-

sized multipolar neuron the dendrites of which occupy a spheroidal field, some 600–800 μ in diameter (Fig 21) There is a characteristi branching pattern in which the secondary dendrites form in bouquets at the major branching points (Fig 25) A few of the dendrites may extend parallel to the collicular surface while others run perpendicularly some as far as the adjacent layers (Figs. 19 27 *2 3* 28 *3*) The axon cannot be traced beyond the initial segment A smaller type of neuron with thin radiating dendrites about 200 μ long also occurs in layer III (Fig 25) The short dendrites do not extend into the neighboring layers (Fig 19 *A*) Such neurons also appear in *layer IV* (Figs 22, *S* 28 *6 7* 29) Other small neurons in layer IV have slightly coarser and more richly branched dendrites (Figs 19 *B* 26) these cells are prominent at the caudal border of the central nucleus More characteristic of layer IV however is the large multipolar neuron with a dendritic field diameter of 800–1 000 μ (Fig 21) The dendritic arrangement varies according to its location in the layer (Fig 20) The most superficial neurons send long dendrites through layer III to

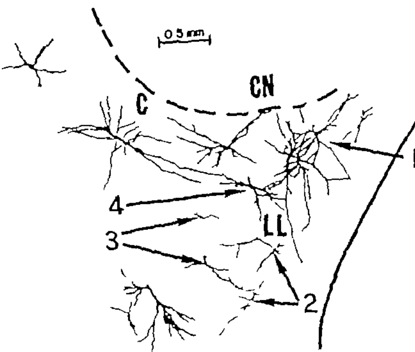

Fig. 31 Dorsal nucleus of the lateral lemniscus (*LL*) and cuneiform area (*C*): detail from *Fig. 7*. *1* ventral-most neurons of the centrolateral nucleus. *2* small-to-medium-sized discoid neurons, oriented with their long axes parallel to the fibers of the lateral lemniscus. *3* small-to-medium-sized discoid neurons with their long axes perpendicular to the fibers of the lateral lemniscus. *4* large stellate neuron of the dorsal nucleus of the lateral lemniscus with its dendrites radiating obliquely across the fibers of the lateral lemniscus.

end in layers I or II (Fig. 23, *2 3 4*). More deeply situated neurons, nearer the central nucleus, often have dendrites coursing parallel to the margin of the central nucleus (Figs. 23 *7* 28, *5* 29) Sometimes two or more dendrites from the same neuron collect, as if in a fascicle, and extend parallel to the margin of the central nucleus in association with axons taking the same path. Less frequently the neurons very near the margin of the central nucleus have spheroidal or oval dendritic fields (Fig. 23 *5 6*). Any of the deeply situated neurons may send dendrites into the peripheral edge of the central nucleus (Figs. 27 *4 5* 28, *2*) or among the most superficial neurons of layer IV (Fig. 22). The largest neurons tend to occur in the middle of layer IV. Their dendrites, extending in various directions in a spheroidal field, often reach the more superficially and deeply situated cells of layer IV (Figs. 22, 20).

The commissural zone contains two basic types of neurons (Fig. 7). More superficially just beneath the unimpregnated margin of the commissural zone are small, highly branched cells, occupying a spheroidal field 400–500 μ in diameter. Frequently one dendrite is more highly branched than the others, as in a bouquet or tuft (Fig. 33 bottom). Some dendrites parallel the paths of the commissural fibers, while other dendrites cross the fibers at right or oblique angles. The axon arises from the perikaryon. These cells might be properly regarded as an interstitial nucleus of the commissure. Peripheral dendritic *growth cones* and dendritic processes, apparently just sprouting from the cell body occur on these cells at all of the ages examined.

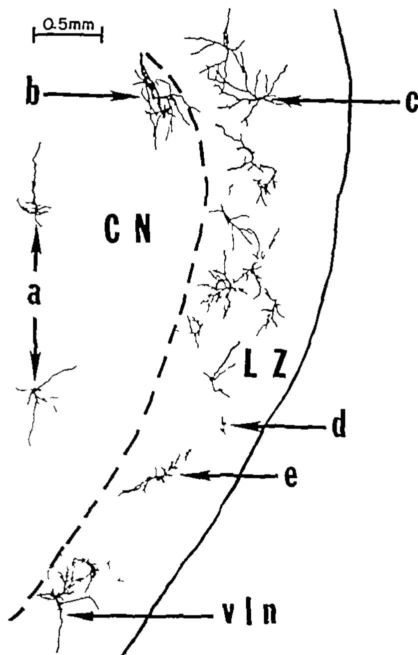

Fig 30 Lateral zone (*LZ*) and ventrolateral nucleus (*Vln*) detail from Fig. 7 *a* disc-shaped neurons of the central nucleus (CN), *b* neurons of the central nucleus at its dorsolateral margin, *c* neuron of layer III of the dorsal cortex adjacent to the lateral zone, *d* small, thin-branched multipolar neuron, embedded among the fibers of the brachium of the posterior colliculus, *e* large multipolar neurons of the lateral zone which resemble the large neurons of layer IV of the dorsal cortex.

sized multipolar neuron the dendrites of which occupy a spheroidal field some 600–800 μ in diameter (Fig. 21) There is a characteristic branching pattern in which the secondary dendrites form in bouquets at the major branching points (Fig 25) A few of the dendrites may extend parallel to the collicular surface while others run perpendicularly some as far as the adjacent layers (Figs. 19 27 *2 3* 28, *3*) The axon cannot be traced beyond the initial segment. A smaller type of neuron with thin, radiating dendrites about 200 μ long also occurs in layer III (Fig 25) The short dendrites do not extend into the neighboring layers (Fig 19 *A*) Such neurons also appear in *layer IV* (Figs 22, *S* 28 *6 7* 29) Other small neurons in layer IV have slightly coarser and more richly branched dendrites (Figs. 19 *B* 26) these cells are prominent at the caudal border of the central nucleus. More characteristic of layer IV however is the large multipolar neuron with a dendritic field diameter of 800–1 000 μ (Fig 21) The dendritic arrangement varies according to its location in the layer (Fig 20) The most superficial neurons send long dendrites through layer III to

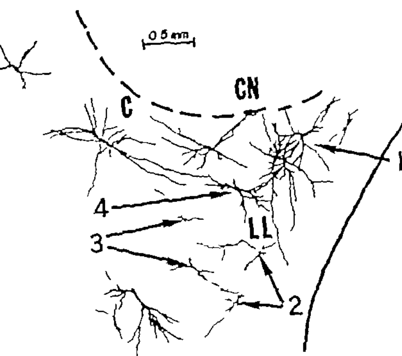

Fig. 31. Dorsal nucleus of the lateral lemniscus (*LL*) and cuneiform area (*C*), detail from Fig. 7. *1.* extralemnal neurons of the ventrolateral nucleus. *2.* small-to-medium-sized discoid neurons, oriented with their long axes parallel to the fibers of the lateral lemniscus. *3.* small-to-medium-sized discoid neurons with their long axes perpendicular to the fibers of the lateral lemniscus. *4.* large stellate neuron of the dorsal nucleus of the lateral lemniscus with its dendrites radiating obliquely across the fibers of the lateral lemniscus.

end in layers I or II (Fig. 23, 2, 3, 4). More deeply situated neurons, nearer the central nucleus, often have dendrites coursing parallel to the margin of the central nucleus (Figs. 23, 7, 28, 5, 29). Sometimes two or more dendrites from the same neuron collect, as if in a fascicle, and extend parallel to the margin of the central nucleus in association with axons taking the same path. Less frequently the neurons very near the margin of the central nucleus have spheroidal or oval dendritic fields (Fig. 23, 5, 6). Any of the deeply situated neurons may send dendrites into the peripheral edge of the central nucleus (Figs. 27, 4, 5, 28, 2) or among the most superficial neurons of layer IV (Fig. 22). The largest neurons tend to occur in the middle of layer IV. Their dendrites, extending in various directions in a spheroidal field, often reach the more superficially and deeply situated cells of layer IV (Figs. 22, 20).

The commissural zone contains two basic types of neurons (Fig. 7). More superficially, just beneath the unimpregnated margin of the commissural zone, are small, highly branched cells, occupying a spheroidal field, 400–500 μ in diameter. Frequently one dendrite is more highly branched than the others, as in a bouquet or tuft (Fig. 33, bottom). Some dendrites parallel the paths of the commissural fibers, while other dendrites cross the fibers at right or oblique angles. The axon arises from the perikaryon. These cells might be properly regarded as an interstitial nucleus of the commissure. Peripheral dendritic growth cones and dendritic processes, apparently just sprouting from the cell body, occur on these cells at all of the ages examined.

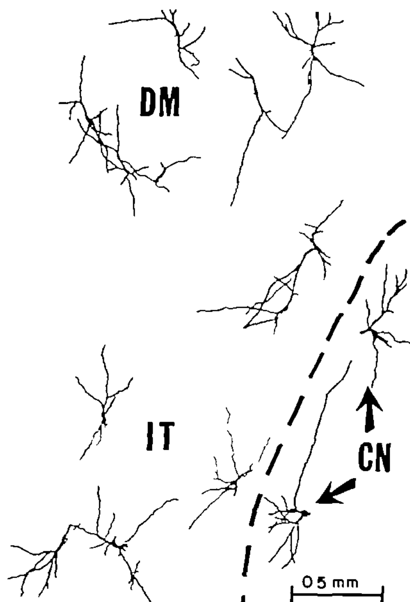

Fig 3 Dorsomedial nucleus (*DM*) and medial intercollicular tegmentum (*IT*): detail from Fig. 7

In Nissl stained sections there is a small group of neurons in the midline overriding the superficial strands of the commissure (Fig 2) This nucleus is not impregnated in the present preparations (Fig 3) although it has been observed in Golgi impregnations of the cat

The larger neurons in the commissural zone occupy more ventral or medial positions (Fig 7) This type of cell, with a dendritic field of 500–600 μ in diameter has 4–6 major branching points (Fig 19 *E*) One or two dendrites usually are parallel to the commissural fibers, while the remaining dendritic branches cross the commissural fibers at right angles. The longest dendrite appears somewhat thicker than the rest and usually parallels the commissural fiber path. Each dendrite has only one or two secondary branches, undergoes little tapering and has a fluffy appearance, due to many small appendages. The axon takes off in a dorsal direction The most ventral cells (Fig 3, top) resemble the neurons typically found in the peri-collicular tegmentum

Peri-collicular tegmentum The neurons of the midbrain tegmentum, e g., the small-to-mediumsized neurons of the *cuneiform area* are characterized by relatively few long, slender straight infrequently branched dendrites usually without prominent spines or append-

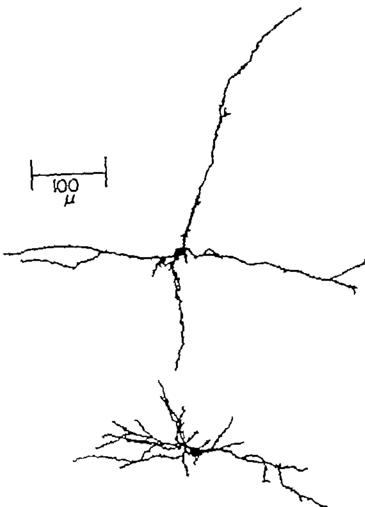

Fig. 31. Intercollicular area associated with the commissure of the posterior colliculus from Fig. 7. Large (top) and small (bottom) types of neurons. Note the terminal dendritic growth cones at the tip of the right-hand dendrite of the large neuron and at the incipient branch half-way along the upper dendrite. Golgi-Cox, *frontal section, 55 year old man.*

ages, whereas the tectal neurons typically have many more dendrites, which are shorter more highly branched, and more compactly arranged (Fig. 7). Since the commissural zone *contains neurons resembling the tegmental* type to some extent this zone could even be regarded as a tegmental region or perhaps a transitional region between tectum and tegmentum. Likewise the regions just medial and just lateral to the central nucleus contain some neurons that are more typically tegmental in form and some that are more typically tectal. Nevertheless, we have included these pericollicular groups in the *tegmentum*, since, unlike the commissural zone, they receive projections from the spinal cord in the cat and opossum. (Morest, 1966 *b*).

The intercollicular tegmentum appears as a thin strip of tegmental neurons extending *anterodorsally from the cuneiform area* between the medial aspect of the central nucleus and the central gray (Fig. 7). Anteriorly it extends to the roof of the midbrain as a thin *tongue of tegmentum, separating the anterior* from the posterior colliculus (Fig. 6). It contains small neurons, similar in form to those of the cuneiform area (Fig. 32).

The dorsomedial nucleus appears to be a specialized aggregation of the medial intercollicular tegmentum, wedged in the angle

formed by the central nucleus, dorsal cortex commissural zone and central gray (Fig 7) The neurons of the dorsomedial nucleus resemble tegmental cells but have thinner more delicate dendrites with more branches than those of the adjacent tegmentum (Fig 32) This nucleus seems to stand out from the rest of the intercollicular zone by virtue of the greater packing density of its cells and the more compact arrangement of their processes

The lateral zone of the peri-collicular tegmentum resembles the intercollicular tegmentum in that it contains many small neurons of the tegmental type which appear to be an anterolateral extension of the cuneiform area (Fig 7) Anteriorly the lateral tegmental cells merge with the intercollicular tegmentum curving around the anteromedial aspect of the central nucleus, so that in a sense, the tegmental type of neurons in the lateral zone could be regarded as the lateral intercollicular tegmentum The lateral zone occupies the lateral surface of the posterior colliculus (Fig. 30) It extends from the dorsal nucleus of the lateral lemniscus and *pedamentum saguli*, ventrally and posterolaterally to the dorsal cortex and brachium of the posterior colliculus, dorsally and anterolaterally The fibers of the brachium gather in the margin of the lateral zone, where its cells merge with the small multipolar neurons of the interstitial nucleus of the brachium (Fig 30 *d*) Many of the neurons, especially the largest ones (Fig 30 *e*) have a more distinctly tectal appearance by virtue of their more elaborate dendritic branching pattern The large neurons resemble the large cells of layer IV in the collicular cortex but the latter tend to be smaller and to have thinner more richly branched dendrites Perhaps the large neurons of the lateral zone could be regarded as derivatives of the fourth cortical layer

The ventrolateral nucleus (Fig 7 *vln*) on the ventrolateral border of the central nucleus in the lateral zone is the counterpart of the dorsomedial nucleus in the medial intercollicular tegmentum However the ventrolateral nucleus is conspicuous for its content of very large neurons—the largest in the lateral zone—and smaller ones of tegmental type (Figs. 30 *vln* 31 *1*)

The dorsal nucleus of the lateral lemniscus (Fig 7 *LL*) contains large, medium and small neurons with sparsely branched dendrites, resembling their neighbors in the cuneiform area But the dendritic branching patterns of the dorsal nucleus are more tightly drawn (Fig 31) The small neuron has a flattened dendritic field oriented with its long axis parallel to the fibers of the lateral lemniscus (Fig 31 *2*) whereas the medium sized neuron has a flat dendritic field, arranged perpendicular to the lemniscal fibers (Fig 31 *3*) The large neuron has a stellate dendritic field, radiating obliquely across the lemniscus (Fig 31 *4*)

Discussion

The present study appears to be the first detailed analysis of the neuronal architecture of the human posterior colliculus. The distinction of a central nucleus and a rind or cortex in the mammalian posterior colliculus generally agrees with previous histological accounts with the Golgi method in the cat, dog mouse, and opossum (Ramón y Cajal 1911 Morest, 1964 *b* 1966 *a*, *b* 1969)

The significance of the present findings derives from the dendritic morphology of the constituent neurons. These cells appear to be so stereotyped in the size, shape and branching pattern of their dendrites that they are readily described as populations of fixed morphological types of neurons Thus as in the medial geniculate body (Morest 1964 *a*) one may determine the extent of the typical populations

n greater precision and with considerably re accuracy than would have been possible h the standard methods of Nissl and Wei-t alone. When the observations are com red in detail with those in the cat (Morest, 64 *b* 1966 *a* *b*) and opossum (Morest, 1969), is possible to identify homologous popula-ns of neurons, according to the principles plied to the medial geniculate body (Morest, 965 c). This is possible because the stereo-yped dendritic branching patterns of different neuronal types are relatively consistent in the several mammalian species examined and, in this respect, appear to be conservative in phylogeny Moreover the embryological observations of the temporal sequence and spatial pattern of neurogenesis in the central nucleus and cortex are comparable in the opossum and cat. *Consequently having critically identified the homologous neurons in the cat we may now hope to apply what little is known of the anatomy and physiology of these species to the human auditory system. Further more since the dendrites of neurons generally accommodate the overwhelming preponderance of their synaptic contacts the geometrical properties of the dendrites alone can define certain aspects of central auditory function.*

The cent al nucleus appears to be homologous to the same nucleus previously identified in the cat (Ramón y Cajal, 1911 Morest, 1964 *b*). In both species the large and small disc-shaped neurons and the varieties of stellate cells are quite comparable However in the cat the large disc shaped neurons tend to congregate in the lateral parts of the central nucleus (Morest, 1966 *b*) Neurons with short axons (Golgi type II), as seen in the cat, have not yet been definitely identified in the present material, although Held (1893) and Kölliker (1896) indicate their existence in the human posterior colliculus. The technique used in the present study is not well suited for their impregnation. In the cat, it was proposed that the laminar arrangement of the disc-shaped neurons in parallel with the ascending auditory afferents would provide the optimum basis for preservation of the tonotopic organization of the auditory pathway (Morest, 1964 *c*) This probably agrees with the microelectrode recordings of the sequence of best frequencies of units found in the central nucleus of the cat (Rose Greenwood, Goldberg & Hind 1963) Similar geometric constellations have been correlated with the tonotopic organiza tion of the auditory system in the medial geniculate body (Morest, 1965 *a*) and in the trapezoid and superior olivary nuclei (Morest, 1968). The probable significance of the stellate neurons is less clear In the cat the axons of the stellate neurons have extensively branched collaterals that reach wide sectors of the fibro-dendritic laminae. The elongated variety that extends perpendicularly across the laminae would intercept a wide sector of the afferent fiber spectrum. Hence it might be expected to have a very broad tuning curve. Such an arrangement would favor detection or summation or an averaging of signals over wide segments of the afferent fiber spectrum The stellate neurons could exert widespread influences, inhibitory or excitatory on the indigenous activity of the nucleus. Whether they might be involved in binaural interaction, the summation of stimulus intensities, or regulation of the general levels of spontaneous activity are matters for speculation. It is not certain which types of neurons project to the medial geniculate body although a projection from the disc-shaped cells could account for a colliculo-geniculate correspondence of the tonotopic organization.

The cortex of the posterior colliculus in man and cat is characterized by flat, elongated neurons in the most superficial layer and stellate neurons in deeper layers that are concentric to the convexity of the colliculus. Since the perikarya in successively deeper layers are progressively larger the layers may be delineated in transverse, Nissl- or silver-stained sections. In Golgi preparations homologous types of neurons appear in the corresponding layers of both cat and man. This cortex is

formed by the central nucleus, dorsal cortex commissural zone and central gray (Fig 7) The neurons of the dorsomedial nucleus resemble tegmental cells but have thinner more delicate dendrites with more branches than those of the adjacent tegmentum (Fig 32) This nucleus seems to stand out from the rest of the intercollicular zone by virtue of the greater packing density of its cells and the more compact arrangement of their processes

The lateral one of the peri-collicular tegmentum resembles the intercollicular tegmentum in that it contains many small neurons of the tegmental type which appear to be an anterolateral extension of the cuneiform area (Fig 7) Anteriorly the lateral tegmental cells merge with the intercollicular tegmentum curving around the anteromedial aspect of the central nucleus, so that, in a sense the tegmental type of neurons in the lateral zone could be regarded as the lateral intercollicular tegmentum The lateral zone occupies the lateral surface of the posterior colliculus (Fig 30) It extends from the dorsal nucleus of the lateral lemniscus and pedamentum saguli ventrally and posterolaterally to the dorsal cortex and brachium of the posterior colliculus, dorsally and anterolaterally The fibers of the brachium gather in the margin of the lateral zone where its cells merge with the small multipolar neurons of the interstitial nucleus of the brachium (Fig 30 *d*) Many of the neurons, especially the largest ones (Fig 30 *e*) have a more distinctly tectal appearance by virtue of their more elaborate dendritic branching pattern. The large neurons resemble the large cells of layer IV in the collicular cortex, but the latter tend to be smaller and to have thinner more richly branched dendrites. Perhaps the large neurons of the lateral zone could be regarded as derivatives of the fourth cortical layer

The ventrolateral nucleus (Fig 7 *vln*) on the ventrolateral border of the central nucleus in the lateral zone is the counterpart of the dorsomedial nucleus in the medial intercollicular tegmentum However the ventrolateral nucleus is conspicuous for its content of very large neurons—the largest in the lateral zone —and smaller ones of tegmental type (Figs. 30 *vln* 31 *1*)

The dorsal nucleus of the lateral lemniscus (Fig 7 *LL*) contains large, medium and small neurons with sparsely branched dendrites, resembling their neighbors in the cuneiform area But the dendritic branching patterns of the dorsal nucleus are more tightly drawn (Fig 31) The small neuron has a flattened dendritic field oriented with its long axis parallel to the fibers of the lateral lemniscus (Fig 31 *2*) whereas the medium sized neuron has a flat dendritic field, arranged perpendicular to the lemniscal fibers (Fig 31 *3*) The large neuron has a stellate dendritic field radiating obliquely across the lemniscus (Fig 31 *4*)

Discussion

The present study appears to be the first detailed analysis of the neuronal architecture of the human posterior colliculus. The distinction of a central nucleus and a rind, or cortex in the mammalian posterior colliculus generally agrees with previous histological accounts with the Golgi method in the cat, dog mouse and opossum (Ramón y Cajal, 1911 Morest, 1964 *b* 1966 *a*, *b* 1969)

The significance of the present findings derives from the dendritic morphology of the constituent neurons. These cells appear to be so stereotyped in the size, shape and branching pattern of their dendrites that they are readily described as populations of fixed morphological types of neurons. Thus, as in the medial geniculate body (Morest 1964 *a*) one may determine the extent of the typical populations

neuronal morphology. In the cat these nuclei are the principal collicular termini of the descending pathway from the auditory cortex (Rasmussen, 1964). Since these nuclei are well represented in the human, one may suppose that the descending auditory pathway is also well represented. However no indications of their possible functions may be given, until their efferent connections and some relevant electrophysiological data are available.

The typical neurons of the peri-collicular tegmentum that appear medial to the central nucleus and in the lateral zone, including the medial and lateral intercollicular tegmentum, respectively correspond to similar groups of neurons observed in the cat (Morest, 1966 *b*). These regions of the posterior colliculus are remarkable because they receive projections from the spinal cord and, in the case of the lateral zone from the dorsal column nuclei (Morest, 1966 *b*). Indeed, Campbell (1944) has recorded evoked somatic sensory potentials from a region that may correspond to the lateral zone. These regions also receive axonal collaterals from the auditory pathways. Probably the medial and lateral tegmental regions are extensions of the cuneiform area and lateral mesencephalic tegmentum, which exhibit similar neuronal morphology and similar afferent connections (Morest, 1965 *b*). All of these tegmental regions may provide for the integration of somatic sensory and auditory inputs at the unit level (Huttenlocher 1960). Moreover these regions probably contribute to the lateral tegmental system of the midbrain, which contains the main ascending input to the dorsal division of the medial geniculate body and the rest of the posterior group (Morest, 1965 *b*) where there is electrophysiological evidence for integration of the somatic sensory and auditory inputs by individual neurons (Poggio & Mountcastle, 1960).

The dendritic growth cones commonly observed in the human posterior colliculus may be construed as morphological signs of growth and neuronal plasticity in both the immature and adult brain. These characteristic features have been correlated with the growth activity of dendrites in developing brains (Morest, 1969). In a number of cases dendritic growth cones have been observed in populations of otherwise mature neurons from young adult brains in the cat and opossum (Morest, 1969, 1971). We now report their common occurrence in aged as well as young humans. Our impression is that the dendritic growth cones are rather more common and widespread in the mature posterior colliculus of the present human material than of the opossum. It is not possible at present to decide whether the dendritic growth in mature and aged individuals reflects a continuation of development, perhaps even related to learning processes, or represents a dystrophic reaction to a degenerative process.

Summary

This report gives the detailed analysis of the neuronal architecture of the human posterior colliculus (auditory tectum). The analysis is made on Golgi-Cox impregnations of midbrains from autopsy cases, ranging from 24 weeks of gestation to 74 years of age. The neurons of the posterior colliculus are so stereotyped in the relative sizes, shapes, and branching patterns of their dendrites that they are readily defined as distinctive morphological populations arranged in specific geometrical constellations, namely the central nucleus, the collicular cortex, and the nuclei of the pericollicular tegmentum. Because these morphological features are relatively stable in mammalian phylogeny and embryogenesis, it is possible to identify the homologous populations of neurons in the cat. Thus we may now begin to relate to the human the anatomical and physiological analyses of the homologous

indeed a cortical structure, in the general sense of the term as applied to the marginal gray matter of the cerebrum cerebellum and olfactory bulb In all of these cortices morphologically distinct layers of the neuropil are intercepted to different extents by the various dendrites crossing them and the layers are interconnected. Cytoarchitectonic studies have confused the cortex of the posterior colliculus with the posterior extent of the anterior colliculus (e g Huber & Crosby 1943) or have apparently relegated it to a narrow strip of tissue associated with the myelinated fiber capsule covering the surface of the tectum (e g Kölliker 1896 Winkler 1921 Riley 1943 Berman 1968 Van Noort [2] 1969) or have ignored it (e g Held 1893 Dejerine 1895 Valeton, 1908 Sterzi 1915 Olszewski & Baxter 1954) The present findings agree with the very brief account of the posterior colliculus given by Ramón y Cajal (1911) in small mammals. In fact, the cortex occupies a large portion of the posterior colliculus Although the relative proportions of the cortex and central nucleus may be comparable in man and cat the cortex appears much smaller in the opossum The cortex is sharply distinguished from the anterior colliculus and neighboring regions by its neuronal architecture and by different afferent connections as well (Morest 1966 a b)

The afferent connections of the cortex of the posterior colliculus are not completely known (see Morest, 1966 a) In the cat auditory axons, ascending primarily to the central nucleus send collaterals to layer IV along with the collaterals of the efferent axons of the central nucleus Thus layer IV is in a position to integrate elements of both the input and output of the central nucleus. The superficial layers receive projections from more anterior levels of the brain The neurons of layer III are best situated to integrate elements of both the ascending and descending pathways, especially by way of intrinsic connections of the neurons of layers II and IV which receive the heaviest exogenous projections. The pattern of intrinsic connections would permit layer III to monitor input and output activity in all other layers Thus the patterns of neural activity that can be generated by the cortex are limited by the spatial patterns of its intrinsic organization How these patterns may relate the posterior colliculus to functions of the auditory system such as the acoustic reflexes or the integration of the ascending and descending auditory pathways, must depend in part on the details of the efferent projections of the posterior collicular cortex (Morest, 1966 a, unpublished)

In cases of asphyxia neonatorum of monkeys the central nucleus is often destroyed bilaterally while the cortex of the posterior colliculus is spared (Ranck & Windle 1959) Such lesions do not necessarily cause deafness however a detailed auditory evaluation was not reported On the other hand Bechterew (1895) had long ago observed that only deep lesions of the posterior colliculus, presumably involving the central nucleus, produced gross hearing losses in rats, rabbits, and guinea pigs, while superficial lesions did not On the basis of behavioral studies (Jane, Masterton & Diamond, 1965) it has been suggested that the apex of the posterior colliculus, apparently including its cortex primarily may somehow affect the ability of cats to attend to acoustic stimuli However these investigations have not specifically defined the role of the cortex of the posterior colliculus In one reported case electrical stimulation of the surface of the posterior colliculus in a human resulted in no conscious sensation (Simmons, Mongeon Lewis & Huntington 1964) This intricate structure deserves more attention in physiological and pathological studies of the posterior colliculus

The dorsomedial and ventrolateral nuclei may be regarded as the homologues of the dorsomedial and lateral nuclei respectively in the cat (Morest, 1966 b) on the basis of their

---

Perhaps the diagrams of the dorsal part of the central nucleus of this uthor correspond to the corte in the cat, but his cytoarchitectonic description does not.

neuronal morphology. *In the cat these nuclei are the principal collicular terminal of the descending pathway from the auditory cortex* (Rasmussen, 1964). Since these nuclei are well represented in the human, one may suppose that the descending auditory pathway is also well represented. However no indications of their possible functions may be given, until their efferent connections and some relevant electrophysiological data are available.

The typical neurons of the peri-collicular tegmentum that appear medial to the central nucleus and in the lateral zone, including the medial and lateral intercollicular tegmentum, respectively correspond to similar groups of *neurons observed in the* cat (Morest, 1966 *b*). These regions of the posterior colliculus are remarkable because they receive projections from the spinal cord and, in the case of the lateral zone, from the dorsal column nuclei (Morest, 1966 *b*). Indeed, Campbell (1944) has recorded evoked somatic sensory potentials from a region that may correspond to the lateral zone. These regions also receive axonal collaterals from the auditory pathways. Probably the medial and lateral tegmental regions are extensions of the cuneiform area and lateral mesencephalic tegmentum, which exhibit similar neuronal morphology and similar afferent connections (Morest, 1965 *b*). All of these tegmental regions may provide for the integration of somatic sensory and auditory inputs at the unit level (Huttenlocher, 1960). Moreover these regions probably contribute to the lateral tegmental system of the midbrain, which contains the main ascending input to the dorsal division of the medial geniculate body and the rest of the posterior group (Morest, 1965 *b*), where there is electrophysiological evidence for integration of the somatic sensory and auditory inputs by individual neurons (Poggio & Mountcastle, 1960).

The dendritic growth cones commonly observed in the human posterior colliculus may be construed as morphological signs of growth and neuronal plasticity in both the immature and adult brain. These characteristic features have been correlated with the growth activity of dendrites in developing brains (Morest, 1969). In a number of cases dendritic growth cones have been observed in populations of otherwise mature neurons from young adult brains in the cat and opossum (Morest, 1969, 1971). We now report their common occurrence in aged as well as young humans. Our impression is that the dendritic growth cones are rather more common and widespread in the mature posterior colliculus of the present human material than of the opossum. It is not possible at present to decide whether the dendritic growth in mature and aged individuals reflects a continuation of development, perhaps even related to learning processes, or represents a dystrophic reaction to a degenerative process.

Summary

This report gives the detailed analysis of the neuronal architecture of the human posterior colliculus (auditory tectum). The analysis is made on Golgi-Cox impregnations of midbrains from autopsy cases, ranging from 24 weeks of gestation to 74 years of age. The neurons of the posterior colliculus are so stereotyped in the relative sizes, shapes, and branching patterns of their dendrites that they are readily defined as distinctive morphological populations arranged in specific geometrical constellations, namely the central nucleus, the collicular cortex, and the nuclei of the pericollicular *tegmentum*. Because these morphological features are relatively stable in mammalian phylogeny and embryogenesis, it is possible to identify the *homologous populations* of neurons in the cat. Thus we *may now* begin to relate to the human the anatomical *and physiological* analyses of the homologous

indeed a cortical structure, in the general sense of the term as applied to the marginal gray matter of the cerebrum cerebellum, and olfactory bulb In all of these cortices morphologically distinct layers of the neuropil are intercepted to different extents by the various dendrites crossing them and the layers are interconnected. Cytoarchitectonic studies have confused the cortex of the posterior colliculus with the posterior extent of the anterior colliculus (e g Huber & Crosby 1943) or have apparently relegated it to a narrow strip of tissue associated with the myelinated fiber capsule covering the surface of the tectum (e g Kölliker 1896 Winkler 1921 Riley 1943 Berman 1968 Van Noort[2] 1969) or have ignored it (e g Held, 1893 Dejerine 1895 Valeton 1908 Sterzi, 1915 Olszewski & Baxter 1954) The present findings agree with the very brief account of the posterior colliculus given by Ramón y Cajal (1911) in small mammals. In fact, the cortex occupies a large portion of the posterior colliculus. Although the relative proportions of the cortex and central nucleus may be comparable in man and cat, the cortex appears much smaller in the opossum The cortex is sharply distinguished from the anterior colliculus and neighboring regions by its neuronal architecture and by different afferent connections as well (Morest 1966 *a b*)

The afferent connections of the cortex of the posterior colliculus are not completely known (see Morest, 1966 *a*) In the cat auditory axons, ascending primarily to the central nucleus, send collaterals to layer IV along with the collaterals of the efferent axons of the central nucleus Thus layer IV is in a position to integrate elements of both the input and output of the central nucleus. The superficial layers receive projections from more anterior levels of the brain The neurons of layer III are best situated to integrate elements of both the ascending and descending pathways, especially by way of intrinsic connections of the neurons of layers II and IV which receive the heaviest exogenous projections. The pattern of intrinsic connections would permit layer III to monitor input and output activity in all other layers Thus the patterns of neural activity that can be generated by the cortex are limited by the spatial patterns of its intrinsic organization How these patterns may relate the posterior colliculus to functions of the auditory system such as the acoustic reflexes or the integration of the ascending and descending auditory pathways, must depend in part on the details of the efferent projections of the posterior collicular cortex (Morest, 1966 *a*, unpublished)

In cases of asphyxia neonatorum of monkeys the central nucleus is often destroyed bilaterally while the cortex of the posterior colliculus is spared (Ranck & Windle, 1959) Such lesions do not necessarily cause deafness however a detailed auditory evaluation was not reported. On the other hand, Bechterew (1895) had long ago observed that only deep lesions of the posterior colliculus, presumably involving the central nucleus, produced gross hearing losses in rats, rabbits, and guinea pigs, while superficial lesions did not. On the basis of behavioral studies (Jane, Masterton & Diamond 1965) it has been suggested that the apex of the posterior colliculus, apparently including its cortex primarily may somehow affect the ability of cats to attend to acoustic stimuli. However these investigations have not specifically defined the role of the cortex of the posterior colliculus. In one reported case electrical stimulation of the surface of the posterior colliculus in a human resulted in no conscious sensation (Simmons, Mongeon Lewis & Huntington, 1964) This intricate structure deserves more attention in physiological and pathological studies of the posterior colliculus.

The dorsomedial and ventrolateral nuclei may be regarded as the homologues of the dorsomedial and lateral nuclei respectively in the cat (Morest 1966 *b*) on the basis of their

[2] Perhaps the diagrams of the dorsal part of the central nucleus of this author correspond to the cortex in the cat, but his cytoarchitectonic description does not.

neuronal morphology In the cat these nuclei are the principal collicular termini of the descending pathway from the auditory cortex (Rasmussen, 1964). Since these nuclei are well represented in the human, one may suppose that the descending auditory pathway is also well represented. However no indications of their possible functions may be given, until their efferent connections and some relevant electrophysiological data are available.

The typical neurons of the peri-collicular tegmentum that appear medial to the central nucleus and in the lateral zone, including the medial and lateral intercollicular tegmentum respectively correspond to similar groups of neurons observed in the cat (Morest, 1966 *b*) These regions of the posterior colliculus are remarkable because they receive projections from the spinal cord and, in the case of the lateral zone, from the dorsal column nuclei (Morest, 1966 *b*). Indeed, Campbell (1944) has recorded evoked somatic sensory potentials from a region that may correspond to the lateral zone. These regions also receive axonal collaterals from the auditory pathways. Probably the medial and lateral tegmental regions are extensions of the cuneiform area and lateral mesencephalic tegmentum, which exhibit similar neuronal morphology and similar afferent connections (Morest, 1965 *b*) All of these tegmental regions may provide for the integration of somatic sensory and auditory inputs at the unit level (Huttenlocher 1960) Moreover these regions probably contribute to the lateral tegmental system of the midbrain, which contains the main ascending input to the dorsal division of the medial geniculate body and the rest of the posterior group (Morest, 1965 *b*) where there is electrophysiological evidence for integration of the somatic sensory and auditory inputs by individual neurons (Poggio & Mountcastle, 1960)

The dendritic growth cones commonly observed in the human posterior colliculus may be construed as morphological signs of growth and neuronal plasticity in both the immature and adult brain. These characteristic features have been correlated with the growth activity of dendrites in developing brains (Morest, 1969) In a number of cases dendritic growth cones have been observed in populations of otherwise mature neurons from young adult brains in the cat and opossum (Morest, 1969 1971) We now report their common occurrence in aged as well as young humans. Our impression is that the dendritic growth cones are rather more common and widespread in the mature posterior colliculus of the present human material than of the opossum. It is not possible at present to decide whether the dendritic growth in mature and aged individuals reflects a continuation of development, perhaps even related to learning processes, or represents a dystrophic reaction to a degenerative process.

Summary

This report gives the detailed analysis of the neuronal architecture of the human posterior colliculus (auditory tectum) The analysis is made on Golgi-Cox impregnations of midbrains from autopsy cases, ranging from 24 weeks of gestation to 74 years of age. The neurons of the posterior colliculus are so stereotyped in the relative sizes, shapes, and branching patterns of their dendrites that they are readily defined as distinctive morphological populations arranged in specific geometrical constellations, namely the central nucleus, the collicular cortex, and the nuclei of the pericollicular tegmentum. Because these morphological features are relatively stable in mammalian phylogeny and embryogenesis, it is possible to identify the homologous populations of neurons in the cat. Thus we may now begin to relate to the human the anatomical and physiological analyses of the homologous

indeed a cortical structure in the general sense of the term as applied to the marginal gray matter of the cerebrum, cerebellum and olfactory bulb In all of these cortices morphologically distinct layers of the neuropil are intercepted to different extents by the various dendrites crossing them and the layers are interconnected Cytoarchitectonic studies have confused the cortex of the posterior colliculus with the posterior extent of the anterior colliculus (e g., Huber & Crosby 1943) or have apparently relegated it to a narrow strip of tissue associated with the myelinated fiber capsule covering the surface of the tectum (e g Kölliker 1896 Winkler 1921 Riley 1943 Berman 1968 Van Noort [2] 1969) or have ignored it (e g Held 1893 Dejerine, 1895 Valeton 1908 Sterzi, 1915 Olszewski & Baxter 1954) The present findings agree with the very brief account of the posterior colliculus given by Ramón y Cajal (1911) in small mammals. In fact, the cortex occupies a large portion of the posterior colliculus Although the relative proportions of the cortex and central nucleus may be comparable in man and cat, the cortex appears much smaller in the opossum The cortex is sharply distinguished from the anterior colliculus and neighboring regions by its neuronal architecture and by different afferent connections as well (Morest 1966 *a b*)

The afferent connections of the cortex of the posterior colliculus are not completely known (see Morest 1966 *a*) In the cat auditory axons, ascending primarily to the central nucleus, send collaterals to layer IV along with the collaterals of the efferent axons of the central nucleus. Thus layer IV is in a position to integrate elements of both the input and output of the central nucleus. structures of the cat Furthermore since the dendrites of neurons accommodate the preponderance of their synaptic contacts the geometrical properties of the dendrites must define certain aspects of central auditory function The central nucleus contains neurons *with disc shaped dendritic fields* arranged in parallel layers that interdigitate with the ascending auditory axons Such an arrangement provides the optimum basis for preservation of the tonotopic organization of the ascending auditory pathway Stellate neurons intercept the fibro-dendritic layers at right angles, so as to foster a more widespread reaction with the afferent auditory spectrum and may be involved in binaural or amplitude distinctions. The *collicular* cortex consists of distinct layers of neurons, which differ morphologically but which interconnect the layers by their dendrites and axons The intrinsic organization of the collicular cortex and its relationships to the collaterals of extrinsic afferent fibers would permit it to monitor the inputs and outputs of the *ascending* and descending auditory pathways of the midbrain, which are perhaps involved in the integration of acoustic reflexes. The neuronal groups of the peri-collicular tegmentum may *provide for interactions of* the auditory and somatic sensory pathways, with which they are connected by way of the ascending sensory lemnisci and descending corticotectal and tecto-reticular tracts The dendritic growth cones commonly observed in the posterior colliculus provide morphological evidence of growth and neuronal plasticity in the brains of immature, adult and aged humans The anatomical findings have significance for the functional interpretation of pathological and behavioral studies of the central auditory system

I Introduction

Approximately 8 500 000 Americans have either bilateral or unilateral hearing impairments of handicapping magnitude. There are approximately 40 000 deaf individuals between the ages of 5 and 18 years in the United States, a number representing a prevalence of about 88 per 100 000 children in this age range. Most deafness is congenital or is acquired relatively early in life (Carhart, 1969).

The goal of this study is to develop a laboratory animal for the study of congenital deafness. The golden hamster possesses features that make it a desirable animal for future research. These include a gestation period of 16 days, ease of obtaining timed matings, large litters, and susceptibility to certain drugs and viruses (Ferm, 1965 1967).

Many leading authors in otologic research and programmatic statements from authoritative public agencies, e g. National Institute of Neurological Diseases and Stroke and The Deafness Research Foundation, have emphatically stressed the dire need for more information in many areas basic to otologic practice These research needs include investigations in the embryological development of the inner ear fine anatomical detail with electron microscopy and cochlear pathology In specific demand should be ear specimens that are identified with sensori-neural deafness, the sequelae of viral infections, rubella, mumps-induced deafness, congenital deafness, cochlear otosclerosis, Menière's disease, and noise-induced nerve deafness. Many advances have been made in middle ear surgery for the relief of diseases of the conductive mechanism. In contrast, practically nothing is known for treating inner ear disease, with the exception of syphilis and Menière's disease. The vast majority of genetic, degenerative, systemic, and symptomatic inner ear lesions are completely beyond any rational treatment.

Once details of the hamster ear are known and the developmental timing of each structure is ascertained, a comparison to human ear development can be made The hamster can then be used as an experimental laboratory model to study the effects of viruses and drugs on ear development in the offspring of females treated during varying stages of gestation. The agents employed can be timed, their mode of damage studied (hemorrhage arrest of development, degeneration, etc.) and the severity of the lesion determined. Genetic factors in inbred strains can also be studied. Ten mutant genes have been described in the hamster eight of which are autosomal and two are totally X linked. All produce their most obvious effect on coat color although three have been found to be associated with morphological defects (Robinson, 1968).

The goals of these studies will be the investigation of any conceivable agents causing damage to the ear One application of these studies to humans is to reduce the incidence of hereditary prenatal, and postnatal degenerative types of deafness.

ttm	*tensor tympani muscle*
VII	facial nerve
VIII	auditory nerve fibers

(*c*) Neonatal disorders

Most of the information we have about the pathology of kernicterus, anoxia, and hypoxia concerns the central nervous system, little is known about the morphological changes within the cochlea. It is possible that animal experiments could be performed in which hyperbilirubinemia deafness is produced and the pathological changes are identified.

(*d*) Congenital hereditary disorders

It is now well established that deafness is a common manifestation of many types of hereditary disorders, particularly the inborn errors of metabolism. Little is known about the morbid anatomy of progressive heredodegenerative sensorineural hypoacusis.

Much more detail is given in this chapter of the report from the National Institute of Neurological Diseases and Stroke, which covers all the areas of hearing disorders and needs for research in each specific area. Only those areas directly related to this study were included here. The most impressive message in this comprehensive report was felt to be what is the obvious, but sometimes overlooked fact, that information concerning pathological conditions, and their effects can only be interpreted and understood by appropriate comparison to data concerning the normal system.

THE PROBLEM OF EARLY INNER EAR DISEASE

Many attempts have been made in the past to solve the complexity of formulating a uniform classification of congenital hearing loss (Ormerod, 1960; Fraser 1964; Beal et al., 1967; Paparella & Winter 1968, and others). This study will refer to the term congenital in its strict definition—present at birth, and specifically to an anomaly of the middle and/or inner ear. The classification used will be as follows. (1) Hereditary; (2) Acquired *in utero*; (3) Acquired during birth.

This problem is elucidated further in more detail by Lindsay (1967); Kelemen (1965); Lindsay & Matz (1966); Cohn et al. (1968); and others. They find that the histopathological differentiation between genetically-determined and acquired types of congenital deafness often cannot be made. Altmann (1950) discussed a classification made by Steurer in 1926 which distinguishes between two types of inner ear deafness on the basis of the anatomic findings. One with regressive changes in the end-organ, the cochlear nerve, and its pathways, and the other with evident developmental anomalies only in the cochlea. He felt that the regressive changes develop either spontaneously leading to developmental anomalies and forming the anatomic basis of inherited deafness, or secondarily from extrinsic factors, the basis of acquired deafness. The anatomic picture must be differentiated from all known pictures of the different stages of spontaneous or secondary regressive changes of the inner ear.

The following classification has been rather universally accepted as providing a classical description of defects in fetal development or aplasia of the ear. This classification has been described by numerous authors for many years. For the sake of brevity the outline will be summarized from the presentations by Scheibe (1892); Altmann (1950, 1968); Ormerod (1960); Beal et al. (1967); Schuknecht (1967); Cohn et al. (1968); Gussen (1968); Paparella & Winter (1968). The order of presentation demonstrates the degree of agenesis in each type.

1. Total labyrinthine agenesis—Michel type. Complete lack of development of the internal ear first described in 1863 by Michel.

2. Cochleo-vestibular dysgenesis—Mondini-Alexander type: Development of only a single, flattened tube representing the basal coil of the cochlea with comparable underdevelopment of the vestibular system. Mondini gave the original description in 1791 of involvement of the cochlear bony structure as well as the length of the membranous cochlea. In 1907 Alexander added to this a description of malformation of the endolymphatic duct and sac.

3. Cochleo-vestibular malformation—Bing-

II Review of the Literature

A report prepared and published by the Subcommittee on Human Communication and its Disorders of the National Institute of Neurological Diseases and Stroke (Carhart, 1969) had the following objectives (1) to define the extent of the field of human communication and its disorders (2) to review the present status of research in human communication and its disorders, and (3) to outline unresolved problems and unmet needs with recommendations as to their solution Chapter 3 is entitled Research on Hearing and was prepared from information obtained by the Subcommittee with the aid of 68 consulting authorities in this area. Certain portions pertinent to the research of the literature of this thesis will be summarized

1 RESEARCH NEEDS

(a) Embryological development

Our understanding of the embryological development of the ear in relation to its function is at an elementary stage Among mammals only a few groups of animals—opossums, rats, mice and rabbits—have been examined sufficiently to show in a general way the course of structural differentiation and the development of effective hearing Many details are lacking and we need especially to understand the conditions that bring about the first stages of function Our knowledge of the development of the human ear is meagre and we know almost nothing about the functional relations Our uncertainty extends through the fetal period into the period of infancy and early childhood Here the embryological problems merge with problems of communication

Further work needs to be done on the embryology of the human ear and likewise on the ear of a number of animal species. This study should lead to a general comprehension of the embryology of the vertebrate ear Of particular interest is the series of developmental changes that mark the first emergence of auditory function and the refinements of performance up to the adult stage Of great importance is the study of hearing in infancy and its growth during the first days, months, and years of life Eisenberg (1970) has even more recently confirmed the findings of the Subcommittee in that there is a shocking paucity of normative information" on the development of hearing in early life This research should correlate anatomical and neural changes with changes in auditory function and general behavior and changes in the adequacy of communication

(b) Prenatal disorders

Additional new information on maternal viral infections and their effect on the fetus is needed. While the histopathological picture of aural embryopathy from maternal rubella is accumulating rapidly many other viruses most likely also affect the fetal hearing organ and may be responsible for many of the congenital hearing losses termed sporadic hereditary hearing loss.

Much more information is also needed about the influence of teratogenic drugs As the medical profession is continuously deluged by a growing array of new medications, advocated by the pharmaceutical houses for many ailments, there is continuing need for careful study of the effects of certain new drugs on the developing embryo

be classified into at least three types. The aplasias, characterized by varying degrees of incomplete development of the inner ear· the heredodegenerations, in which there is a progressive loss of hearing after the inner ear has developed normally· the chromosomal aberrations. Heredodegenerative deafness may occur alone or in combination with other abnormalities, in which case they are known as syndromes. These syndromes are often hereditary sometimes congenital sometimes abiotrophic, and sometimes mixed (Schuknecht, 1967).

Proctor & Proctor (1967) estimate that one third to one-half of all cases of congenital deafness are due to hereditary deafness. A more definite figure of one-half is given by Konigsmark (1969 *b*). It is estimated that in about 30–40% of all children born deaf the cause is unknown More children are surviving now because of better pre and post-natal care and because of general improvements in the care of the handicapped. For this reason the number of children with dual handicap (e.g. deafness with cerebral palsy deafness with low mental ability deafness with various congenital malformations) is increasing.

The abnormality of the inner ear in congenital deafness, which has been either directly damaged or incompletely developed, is irreversible The only hope, at present, in respect to direct treatment lies in preventive measures. Effort should be made to evolve preventive measures, for which more fundamental research is required. For example, it is important that the frequency and tendency of various known causes should be investigated (Livingstone, 1964).

Proctor & Proctor (1967) have listed 39 conditions with hereditary nerve deafness. In their survey they find that 90% of hereditary deafness is inherited as an autosomal recessive, and 10% as an autosomal dominant trait. A substantial number of patients with congenital deafness are homozygous for autosomal recessive mutant genes (Carter 1964). It was indicated in an analysis of a study of deafness by Chung et al. (1959), that about two-thirds of the patients were homozygous for autosomal recessive genes about one fifth were heterozygous for dominant mutant genes just a few were caused by sex-linked genes and about one-tenth were deaf from intrauterine and perinatal environmental causes. Most types of hereditary nerve deafness, both autosomal dominant, recessive, and from chromosomal aberrations, occur with associated defects (Schuknecht, 1967) However most cases of hereditary childhood deafness are not associated with an identified syndrome. Thyroid metabolism defect with or without goiter is the most commonly associated trait and appears to result from a variety of thyroid metabolism deficiencies of the recessive type. Brown (1967) states that disturbances of pigment metabolism are the only syndromes presently believed to be associated with dominant childhood deafness.

Analysis of the anatomic findings in man is aided by the fact that in certain animals, such as cats, dogs, guinea pigs and mice, inherited forms of deafness are known to exist (Altmann, 1950). There is a rapidly increasing knowledge of morphology of inherited deafness in mice and other rodents and in many respects the morphological findings are very similar or even identical with those in man, cats, dogs, or other animals except for the fact that in the majority of the strains of deaf rodents the hearing loss *is associated with* locomotor anomalies of a kind so *far never* observed in man, cats or dogs (Altmann, 1964 Deol, 1968) The locomotor disorders result from cerebellar degeneration, peripheral (vestibular), central, or both. In man the vestibular system is often normal in genetic deafness.

The golden hamster has been employed in several diverse areas of genetic investigation (Robinson, 1968) However there have been no reports of functional, embryological, or anatomical studies in relation to hereditary deafness. Magalhaes et al. (1962 *b*) studied heterochromia iridis in the hamster one of the

Siebenmann type The bony labyrinth is well formed, but the membranous part and particu larly the sense organ is poorly developed Siebenmann first described this type in 1902, with Bing adding associated abnormalities of the central nervous system in 1907

4 Cochleo-saccular hypoplasia—Scheibe type The vestibular portion of the inner ear is developed and functioning. Malformation is restricted to the membranous cochlea and saccule in a normal bony labyrinth Scheibe (1892) described this type, which is the type most frequently found (Deol, 1968)

5 Tympanic malformation—Siebenmann type Changes are found mainly in the middle ear such as typically seen in cases of Swiss cretins

The phylogenesis of the mammalian ear probably began with the lateral line system of fish which was needed to sense movement. The transition from water to land and air environ ment necessitated the development of a sound transformer and impedance matching mechanism The semicircular canals were the first to evolve from the lateral line system and the lagena was the second which later evolved into the cochlea (Taylor 1969)

Since the vestibular apparatus is hundreds of millions of years older than the later de veloped and more highly differentiated cochlear apparatus, it is well understood that for phylogenetic reasons the organs of recent development are far less resistant to disease than are the older organs (Goodhill, 1950)

Knowledge concerning congenital pathologi cal conditions of the ear can only be inter preted and understood by comparison of the normal development and structure of the ear Fraser (1959) terms this the embryologic approach in that knowledge of the abnormal must be based on knowledge of the normal in studying congenital malformations of the ear

3 HEREDITARY DEAFNESS

Hereditary deafness has been classified in many ways including the genetic classification of Martensson (1960) the clinically oriented classification of Kinney (1950) and the pathological classification of Ormerod (1960) Variations of these have been proposed by Goodhill (1950), and others. Konigsmark & McKusick (1966) feel that the simplest or ganization of types of hereditary deafness is based on associated anomalies, since the spe cific genetic defect in most types of hereditary loss results in abnormalities in other systems as well The following structures are involved in different types of familial hearing loss, ex ternal ears integumentary system visual system nervous system skeletal system urin ary system and endocrine system Thus, the types of hereditary deafness can be classified on the basis of associated defects caused by the same gene (Konigsmark 1969 *a*) These are known as syndromes and may be classified endodermal, mesodermal, and ectodermal, according to the combination of anomalies present (Schuknecht, 1967)

Fisch (1959) studied a hereditary syndrome with deafness the most significant clinical symptom but also involving the integumen tary system This study made possible a better understanding of the relation between body pigmentation and hearing. These two systems are both ectodermal in origin and thus closely linked developmentally and functionally and this link may explain some of the mechanisms involved which lead to anomalies appearing simultaneously in both systems. The laby rinth contains pigment for no known purpose, but its absence has been seen in hereditary deafness. Another striking coincidence is the simultaneous affliction of body hair and cochlear hair cells in certain syndromes, such as Waardenburg s syndrome (Waardenburg 1951) There is also a resemblance between the urinary system and inner ear because function of the stria vascularis is somewhat similar to kidney function (Ormerod, 1960)

Genetic factors, like infectious processes, vary greatly in the severity of their effect which is referred to as variability in specific ity Hereditary sensorineural hearing loss may

ard of medical care the possibility cannot, of course, be excluded that other as yet unsuspected, causes exist (Fraser 1964).

(c) Connatal syphilis

An excellent review of the literature on syphilis of the ear is presented by Goodhill (1939). He studied eight cases of congenital syphilis and found no specific variety of hearing loss that could be associated with luetic aural disease. Syphilis may be contracted during the passage of the infant through the birth canal, which would be intranatally acquired, or through hematogenous infection of the fetus through the placenta via the connecting maternal and fetal blood streams, a case of prenatal acquisition.

Karmody & Schuknecht (1966) have found *that there is considerable variation* both in time of onset and type of syphilitic hearing loss, as well as variation in the rapidity of its progression. The onset of early syphilitic deafness in childhood is usually very sudden, bilateral, symmetrical, profound, and not accompanied by marked vestibular symptoms. Hearing loss resulting from congenital lues may appear as early as the first decade or as late as the fifth (Patterson, 1968). Arnold & Ohsaki (1963) reiterated the well-known distinction of connatal syphilis of the ear into an early and late type. The nerve deafness of late connatal syphilis usually does not respond to treponemicidal therapy representing a hypersensitivity phenomenon.

(d) Neonate hyperbilirubinemia

Any condition causing hemolysis can cause a tissue accumulation of indirect bilirubin from hemoglobin breakdown, resulting in jaundice. Among these diseases are: Rh and AB0 incompatability cytomegalic inclusion disease, galactosemia, septicemia (sepsis), biliary atresia, and neonatal hepatitis. The primary cause of erythroblastosis foetalis is *considered to be* the presence of acquired Rh antibodies in the blood of an Rh negative woman (*false* blood transfusion, preceding pregnancy with Rh positive fetus) (Kelemen, 1956) While hyperbilirubinemia *is necessary for* the development of kernicterus, it cannot be considered the sole factor as hypoxia of varying degrees may be a necessary prerequisite for the development of bilirubin deposition in cranial regions (Goodhill, 1967).

In a study by Keaster et al. (1969) sensorineural hearing loss was found to occur with and without other central nervous system abnormalities. Findings from investigations by Matkin & Carhart (1968) *were contradictory* in determining whether congenital hearing losses were the result of anoxia (and thus of central origin), or peripheral, or a combination of both. Crabtree & Gerrard (1950) studied the brain stem and temporal bones of a neonate who died of erythroblastosis foetalis. They reported that both organs of Corti, auditory nerve fibers, and ganglion cells were normal. However the brain stem showed that *the cell bodies in both the ventral and dorsal* cochlear nuclei were absent. Damage of this type is thought to be caused by a direct toxic *effect of high bilirubin levels on the brain*, the deafness being due not to involvement of the peripheral auditory apparatus, but of the cochlear nuclei (Fraser 1964). There continues to be controversy over the site of the auditory lesion in Rh incompatibility (Sataloff & Vassallo, 1970). In his survey of congenital and acquired *cytomegalic inclusion infection*, Hanshaw (1966) reported at least one case of deafness in 13 infants afflicted by cytomegalic virus, after Hanshaw et al. (1965) had mentioned one case of congenital deafness among 9 virus-positive children.

(e) Toxoplasmosis

This has been well documented as an infection in pregnancy causing inner ear *anomalies* in fetuses (Kelemen, 1958 *b*). Toxoplasmosis is a ubiquitous infection so that elucidation of its role as a source of congenital deafness is *of first importance* (Kelemen, 1961).

features found in man with Waardenburg's syndrome (Waardenburg 1951) All the animals in which the trait was observed were belted or banded with white, which is a form of dominant white spotting in the hamster In both men and mice heterochromia iridis is sometimes associated with spotting genes

In hamsters, heterochromia iridis has not yet been observed in individuals with full or wild type pigmentation, or in animals in which the coat is entirely white The trait does not act as either a simple dominant or simple recessive and is as common in males as in females (Magalhaes et al 1962 *b* Robinson, 1968)

4 AURAL EMBRYOPATHIES (Human)

(*a*) Rubella

Hearing defects in the progeny of mothers who contracted rubella in the first trimester of pregnancy is a well studied phenomenon (Kelemen, 1966) The first description of a rubella epidemic was by Gregg (1941) which occurred in Australia in 1939–1941 He gave the first description of congenital cataracts associated with congenital heart disease in babies whose mothers had contracted rubella in the first trimester of pregnancy Swan et al. (1943) were the first to associate deaf mutism as a component of this entity in these rubella babies from the Australian epidemic A review of the congenital defects occurring in this epidemic were summarized by Swan (1944) Deafness associated with the rubella syndrome occurs frequently yet its pathogenesis is not established (Ingalls et al 1960 Dunnington, 1968) Intra uterine rubella infection may result in developmental retardation congenital malformations, and chronic inflammation in several visceral organs in addition to the classic triad of cataracts, deafness, and patent ductus arteriosus (Esterly and Oppenheimer 1969)

Hardy et al. (1969) recently observed that deafness and infant morbidity is not confined to maternal infection in the first trimester Fetal infection may take place at any time during pregnancy and long after delivery More recently Sever (1970) stated that rubella virus usually persists for 6 months after birth and has been reported by Plotkin (1970) to persist until 3 years of age in the lens of children with congenital cataracts. Sever (1970) feels that one possible viral mechanism of rubella infection through which organ development is disrupted is damage to blood vessels. A child who has a partial hearing loss at 5 or 6 years of age when the blood vessels damaged *in utero* by rubella virus hemorrhage under the increasing stress of the child's growth. Vascular vulnerability and insufficiency of the inner ear persists from the moment of first assault and manifests itself at any intra uterine or extra-uterine period (Kelemen, 1966)

A causal connection between maternal rubella deafness and the tendency toward hereditary hearing defects in the parents and their families was investigated by Anderson et al. (1970) in 26 out of 257 cases that were initially surveyed for maternal rubella hearing impairments. The results of this study indicated that a great number of the parents were carriers of genes for deafness and an overwhelmingly high incidence of hereditary deafness was present in the parents families. These authors concluded that genetic disposition for hearing impairment thus appears to be a prerequisite for maternal rubella deafness In man it would seem to be the first time that a connection has been found between a specific genetic defect in an organ and an exogenous agent—in this case rubella virus—acting on the same organ

(*b*) Measles

Lindsay & Hemenway (1954) reported that congenital deafness may be caused by measles during pregnancy but this is less common than maternal rubella Rubella is the only substantial known cause of prenatally acquired deafness today in countries with a high stand

after thalidomide exposure. Rosendal (1965) reported a case of a woman who had taken thalidomide between the 24th and 34th days ($3^1/_2-4^1/_2$ weeks) after conception. The infant died at 4 months of age. Histological study of the temporal bones revealed absence of the internal auditory meatus and of the acoustic and vestibular nerves bilaterally. A case of congenital labyrinthine aplasia in the offspring of a woman who had taken thalidomide 25 days (3 /₂ weeks) after conception was reported by Jørgensen et al. (1964). The infant died at 4 months of age and histological study was made of the temporal bones. Livingstone (1965) did a tomographic study of the labyrinth of children with thalidomide embryopathy and found arrested development of the inner ears with marked dilation of the semicircular canals.

(b) Lysergic acid diethylamide (LSD)

LSD has been suspected as having a causal relationship in newborn infants with deformities. Smart & Bateman (1968) made a thorough review of the literature on chromosomal damage and teratogenic effects caused by LSD in humans and animals. They came to the conclusion that the evidence for the teratogenic effect of LSD is very strong but somewhat ambiguous and incomplete.

Zellweger et al. (1967) reported a case of a pregnant woman who had taken LSD on the 25th day (3 / weeks) after her last menstrual period and three times between the 45th and 98th days (6 / – 14 weeks). Her husband had also taken LSD. His findings in the infant was a malformed right leg which included lack of fibula, anterior bowing of the shortened tibia, absence of the lateral rays of the foot, and dislocation of the hip. Chromatid breaks were found in the peripheral white blood cells of the infant and both parents. Hsu et al. (1970) reported a case where chromosomal analysis of the infant revealed trisomy 13 with a D/D translocation. The parents had used LSD prior to conception but not during pregnancy. The clinical findings suggested the combination of defects compatible with the Trisomy 13 syndrome.

Eighty to 85% of those using LSD manifest an unusually high incidence of chromosomal rearrangement (N.Y. Med. Soc. 1968). Similar chromosomal abnormalities have been found in some infants of women who took LSD during pregnancy. Thus, the danger of genetically induced damage in LSD users or their progeny is raised.

6. OTOTOXIC DRUGS

The ototoxicity of streptomycin, dihydrostreptomycin, neomycin, kanamycin, framycetin, gentamycin, salicylate, chloroquine, and quinine have been well documented in humans and animals, e.g. cat, monkey, guinea pig, rat (West, 1938; Glorig, 1951; Hawkins, 1959, 1967; Lindsay et al., 1960; Ward & Fernandez, 1961; Benitez et al., 1962; McGee & Olszewski, 1962; Engstrom & Kohonen, 1965; Kohonen, 1965; Finegold, 1966; Kreis, 1966; DeMoura & Hayden, 1968; Kerr & Schuknecht, 1968; Sataloff & Vassallo, 1970). There is agreement among these authors and others that these drugs have a predilection for the inner ear with resulting sensorineural deafness and/or vestibular disorders. There is also agreement that streptomycin produces a greater toxic effect on the vestibular system, while dihydrostreptomycin is more toxic to the auditory mechanism.

Since many drugs are known to be ototoxic, causing inner ear damage with resulting varied degrees of hearing loss, there seems to be little reason to doubt that congenital deafness may sometimes be caused by large doses of such drugs in pregnant women (Fraser, 1964). Robinson & Cambon (1964) reported on two children whose mothers had taken streptomycin during pregnancy for treatment of tuberculosis. In the first case the mother had been given a dose of 1 g twice weekly between the 6th and 14th weeks of pregnancy. Hearing loss was suspected in the infant at 6 months of age and at 4 years of age the child was

(f) Maternal toxic disease

A number of examples of maternal toxic conditions in the mother have demonstrated abnormal conditions in the ears of fetuses whose mothers had suffered, during the early months of pregnancy from some toxic or endocrine disease These embryopathies include diabetes, pseudohypoparathyroidism nephritis, poliomyelitis and viral pneumonia (Kelemen 1955 *a b* 1957 1958 *b* 1959 1960 Lindsay et al 1953 1954 Hinojosa 1958 Jørgensen 1961) According to Fraser (1964) congenital syphilis, toxoplasmosis and maternal rubella are the only aural embryopathies that are well substantiated

(g) Perinatal causes of deafness

The premature child is especially vulnerable to factors that may lead to deafness which occur in his struggle to adapt to the extra uterine environment (Fraser 1964) Deafness is more frequent in premature babies due to their fragility extra risks in labor and anoxia susceptibility all of which prediospose them to damage to the nerve cells of the cochlea (Harrison 1959) However Fraser (1964) states that anoxia and/or birth injury may also though less often, be responsible for deafness in normally mature children Fisch (1955) demonstrated that a high proportion of children with cerebral palsy have significant hearing losses Injuries within or near the temporal bone may cause hemorrhages in the inner ear (Kelemen 1965)

5 DRUG INDUCED MALFORMATIONS

(a) Thalidomide

Thalidomide was the first apparently non-toxic compound found to be teratogenic (McBride 1963) There can no longer be any doubt as to the causal relationship between the ingestion of thalidomide during pregnancy and congenital defects in the offspring involving not only the limbs but also the ears (Kleinsasser & Schlothane 1964) The results of a study by Lenz & Knapp (1962) suggested that the critical period when thalidomide ingestion may cause damage to the fetus is between the 37th and 50th day after the last menstruation In a few of their cases the time of conception was known and the critical period was from the 27th to 33rd day ($3\,^1/_2 - 4\,^1/_2$ weeks) of pregnancy Kittel & Saller (1964) studied a group of children that had been malformed by their mothers ingestion of thalidomide during pregnancy In this series of ear deformities, thalidomide had been taken around the fifth week of pregnancy suggesting that the teratogenic dose and the time of administration of thalidomide are related. The mode of action of thalidomide is not known but it is more important to know that a substance has a potential for damaging the fetus than to know the mode of action of such agents (Litchfield 1967)

The thalidomide embryopathy comprises a spectrum of widely different types (Smithells, 1965) In some children, the external ears are absent, and the facial and ocular nerves are paralyzed In others deafness due to a gross defect of the inner ear abducens paralysis, and preauricular appendages are the only signs (Lenz, 1966)

D Avignon & Barr (1964) studied 14 children whose mothers had taken thalidomide during the first two months of pregnancy Their findings suggested a complex syndrome with ear deformities, hearing loss, paralysis of the facial, abducens or other oculomotor nerves, paralysis of the soft palate, as well as other malformations of limbs, heart and other organs. It was notable that the syndrome of ear malformations, hearing loss, and cranial nerve paralysis was unaccompanied by limb deformities Kleinsasser & Schlothane (1964) studied in detail 70 children with thalidomide induced ear deformities. Their findings included, in addition to the well known forms of microtia various aplasias and hitherto unknown vestibular anomalies of the inner ear with deafness and absence of vestibular reactions Two cases were reported as the first observations of isolated ear malformations

er thalidomide exposure. Rosendal (1965) ported a case of a woman who had taken alidomide between the 24th and 34th days / –4 ¹/ weeks) after conception. The in- nt died at 4 months of age. Histological udy of the temporal bones revealed absence f the internal auditory meatus and of the coustic and vestibular nerves bilaterally. A ase of congenital labyrinthine aplasia in the ffspring of a woman who had taken tha- idomide 25 days (3 / weeks) after concep- ion was reported by Jørgensen et al. (1964). The infant died at 4 months of age and histological study was made of the temporal bones. Livingstone (1965) did a tomographic study of the labyrinth of children with tha- lidomide embryopathy and found arrested de- velopment of the inner ears with marked dila- tion of the semicircular canals.

(*b*) Lysergic acid diethylamide (LSD)

LSD has been suspected as having a causal relationship in newborn infants with de formities. Smart & Bateman (1968) made a thorough review of the literature on chromo- somal damage and teratogenic effects caused by LSD in humans and animals. They came to the conclusion that the evidence for the teratogenic effect of LSD is very strong but somewhat ambiguous and incomplete.

Zellweger et al. (1967) reported a case of a pregnant woman who had taken LSD on the 25th day (3 / weeks) after her last menstrual period and three times between the 45th and 98th days (6 / –14 weeks). Her husband had also taken LSD. His findings in the infant was malformed right leg which included lack of fibula, anterior bowing of the shortened tibia, absence of the lateral rays of the foot, and dislocation of the hip. Chromatid breaks were found in the peripheral white blood cells of the infant and both parents. Hsu et al. (1970) eported a case where chromosomal analysis of the infant revealed trisomy 13 with a D/D translocation. The parents had used LSD prior to conception but not during pregnancy. The clinical findings suggested the combination of defects compatible with the Trisomy 13 syn- drome.

Eighty to 85% of those using LSD manifest an unusually high incidence of chromosomal rearrangement (N.Y. Med. Soc., 1968). Similar chromosomal abnormalities have been found in some infants of women who took LSD dur ing pregnancy. Thus, the danger of genetically induced damage in LSD users or their progeny is raised.

6 OTOTOXIC DRUGS

The ototoxicity of streptomycin, dihydrostrep- tomycin, neomycin, kanamycin, framycetin, gentamycin, salicylate, chloroquine, and quin- ine have been well documented in humans and animals, e.g. cat, monkey, guinea pig, rat (West, 1938; Glorig, 1951; Hawkins, 1959, 1967; Lindsay et al., 1960; Ward & Fernandez, 1961; Benitez et al., 1962; McGee & Olszewski, 1962; Engstrom & Kohonen, 1965; Kohonen, 1965; Finegold, 1966; Kreis, 1966; DeMoura & Hayden, 1968; Kerr & Schuknecht, 1968; Sataloff & Vassallo, 1970). There is agreement among these authors and others that these drugs have a predilection for the inner ear with resulting sensorineural deafness and/or vestibular disorders. There is also agreement that streptomycin produces a greater toxic ef fect on the vestibular system, while dihydro- streptomycin is more toxic to the auditory mechanism.

Since many drugs are known to be ototoxic, causing inner ear damage with resulting varied degrees of hearing loss, there seems to be little reason to doubt that congenital deafness may sometimes be caused by large doses of such drugs in pregnant women (Fraser, 1964). Ro- binson & Cambon (1964) reported on two children whose mothers had taken strepto- mycin during pregnancy for treatment of tu- berculosis. In the first case the mother had been given a dose of 1 g twice weekly between the 6th and 14th weeks of pregnancy. Hearing loss was suspected in the infant at 6 months of age and at 4 years of age the child was

(f) Maternal toxic disease

A number of examples of maternal toxic conditions in the mother have demonstrated abnormal conditions in the ears of fetuses whose mothers had suffered, during the early months of pregnancy from some toxic or endocrine disease These embryopathies include diabetes, pseudohypoparathyroidism nephritis poliomyelitis, and viral pneumonia (Kelemen 1955 *a b* 1957 1958 *b* 1959 1960 Lindsay et al., 1953 1954 Hinojosa, 1958 Jørgensen 1961) According to Fraser (1964) congenital syphilis toxoplasmosis, and maternal rubella are the only aural embryopathies that are well substantiated

(g) Perinatal causes of deafness

The premature child is especially vulnerable to factors that may lead to deafness which occur in his struggle to adapt to the extra uterine environment (Fraser 1964) Deafness is more frequent in premature babies due to their fragility extra risks in labor and anoxia susceptibility all of which prediospose them to damage to the nerve cells of the cochlea (Harrison 1959) However Fraser (1964) states that anoxia and/or birth injury may also though less often be responsible for deafness in normally mature children. Fisch (1955) demonstrated that a high proportion of children with cerebral palsy have significant hearing losses. Injuries within or near the temporal bone may cause hemorrhages in the inner ear (Kelemen 1965)

5 DRUG INDUCED MALFORMATIONS

(a) Thalidomide

Thalidomide was the first apparently non toxic compound found to be teratogenic (McBride, 1963) There can no longer be any doubt as to the causal relationship between the ingestion of thalidomide during pregnancy and congenital defects in the offspring involving not only the limbs, but also the ears (Kleinsasser & Schlothane, 1964) The results of a study by Lenz & Knapp (1962) suggested that the critical period when thalidomide ingestion may cause damage to the fetus is between the 37th and 50th day after the last menstruation In a few of their cases the time of conception was known and the critical period was from the 27th to 33rd day ($3^1/_2-4^1/_2$ weeks) of pregnancy Kittel & Saller (1964) studied a group of children that had been malformed by their mothers ingestion of thalidomide during pregnancy In this series of ear deformities, thalidomide had been taken around the fifth week of pregnancy suggesting that the teratogenic dose and the time of administration of thalidomide are related. The mode of action of thalidomide is not known but it is more important to know that a substance has a potential for damaging the fetus than to know the mode of action of such agents (Litchfield 1967)

The thalidomide embryopathy comprises a spectrum of widely different types (Smithells, 1965) In some children the external ears are absent, and the facial and ocular nerves are paralyzed In others, deafness due to a gross defect of the inner ear abducens paralysis, and preauricular appendages are the only signs (Lenz, 1966)

D Avignon & Barr (1964) studied 14 children whose mothers had taken thalidomide during the first two months of pregnancy Their findings suggested a complex syndrome with ear deformities, hearing loss, paralysis of the facial, abducens, or other oculomotor nerves, paralysis of the soft palate, as well as other malformations of limbs, heart, and other organs It was notable that the syndrome of ear malformations, hearing loss, and cranial nerve paralysis was unaccompanied by limb deformities Kleinsasser & Schlothane (1964) studied in detail 70 children with thalidomide induced ear deformities Their findings included, in addition to the well known forms of microtia, various aplasias and hitherto unknown vestibular anomalies of the inner ear with deafness and absence of vestibular reactions Two cases were reported as the first observations of isolated ear malformations

20 weeks in the hamster but not in the other animals. The results for the newborn mouse were equivocal. In this study he also included adult albino rats, hedgehogs, and 3-week-old chicks, none displaying virus recovery. The chronic infection of rubella virus in the newborn ferret was also shown by Fabiyi, Gitnick & Sever (1967). In initial experiments by Oxford & Schild (1966), transplacental passage of rubella virus in the hamster could not be demonstrated. Further work in this area by Oxford & Sutton (1968) ga e the same findings. Preliminary studies by Oxford (personal communication) have suggested that even when rubella is inoculated directly into the amniotic sac in utero in rabbits and hamsters, no virus multiplication occurs. However Sever (1970) recently reported runted rabbits produced by infecting the does with rubella virus which persisted in the offspring tissues for many months. Mumps virus was injected intravenously in the pregnant hamster and also did not penetrate the placenta. It did not produce any histopathological lesions in maternal or fetal hamsters (Ferm & Kilham, 1963). It is believed that the viral macromolecules are too large to pass the placental barrier in these animals (Moya & Thorndike, 1962 Mitchell & Woodside, 1967).

(*b*) Thalidomide

In a study by Homburger et al. (1965) pregnant golden hamsters were fed a diet which contained 0.6% thalidomide. This resulted in grossly abnormal fetuses. The New Zealand white rabbit, rats, and mice were found to be sensitive to thalidomide in McBride's (1963) studies on its teratogenic action. No studies were found in the literature describing inner ear malformations from thalidomide in animals.

(*c*) LSD

Pregnant hamsters were injected with lysergic acid diethylamide (LSD), -bromo-D-lysergic acid diethylamide (BOL), and mescaline (MES) on the 8th day of gestation by Geber (1967) and sacrificed on the 12th day. His results showed that LSD MES, and BOL can induce a wide variety of malformations in the hamster embryo. Alexander et al. (1967) injected LSD in rats early in pregnancy which produced runts and increased fetal mortality. Injection late in pregnancy had no obvious effect on the offspring. In contrast to these findings, Warkany & Tokacs (1968) found no abnormalities in the offspring of rats injected with LSD on the 4th and 5th days of pregnancy even though the doses administered were as high as those used by humans. Auerbach & Rugowski (1967) injected mice with LSD on the 6th, 8th, and 9th days of pregnancy. Brain abnormalities were found in embryos when the mother had been injected in the earliest stage, but no gross observable effects occurred when the drug was administered later than the 7th day of gestation. The stage of pregnancy in mice found to be sensitive to embryonic malformations mediated by LSD is a stage equivalent to human pregnancy of 16–22 days.

8. DEVELOPMENT OF THE MIDDLE AND INNER EAR

(*a*) Human

The detailed description of the histogenesis of the developing inner and middle ear has been well presented by Streeter 1907 1918 1945 1948, 1951 Van der Stricht, 1918 Ingalls, 1920 Macklin, 1921 Bartelmez & Evans, 1926 Corner 1929 Bast, 1930 1932, 1936, 1938, 1940, 1942, 1944 1946- Anson, 1946, 1969- Anson et al., 1947 1948 *a* *b* 1955 Anson & Bast, 1946, 1949 1951 1958 Bast & Anson, 1950, 1952 Watzke & Bast, 1950 Richany et al., 1954 Bast et al., 1956 Heuser & Corner 1957 Borghesan, 1965 Van Alyea, 1965 The following is a brief summary of the developing middle and inner ear of the human.

Membranous labyrinth

The otic placode is believed to originate from both surface ectoderm, which forms the epi-

found to have a severe bilateral sensorineural hearing loss and total loss of vestibular function In the second case the mother received 1 g of streptomycin twice weekly during the last 4 months of pregnancy with the same findings in the child as in the first case

Five cases of reduced hearing in children of mothers who had received streptomycin or dihydrostreptomycin during pregnancy have been described since 1950 (Rasmussen 1969) This study showed that the danger of ototoxic damage to the fetus of a mother under treatment with these drugs during pregnancy is slight. However it confirmed earlier reports concerning the risk of hearing damage from treatment with large doses of either of these drugs. Bolletti & Croatto (1958) described a severe form of congenital deafness in a 5-year old girl resulting from streptomycin treatment of the mother during the last 3 months of pregnancy The findings of Conway & Birt (1965) suggested that further work is required to evaluate the risks to the fetus of streptomycin given during pregnancy

Chloroquine phosphate, which is chemically related to quinine may be an ototoxic drug in adults (Sataloff & Vassallo 1970) Matz & Naunton (1968) reported the case of a mother who had taken this drug for the treatment of systemic lupus erythematosus during the first trimestesr of her first, second, and third pregnancies The first child had bilateral profound sensorineural deafness, cerebellar dysfunction and marked bilateral vestibular paresis The second child was profoundly deaf and the third pregnancy resulted in miscarriage Three subsequent pregnancies without treatment with this drug produced normal children with normal hearing

7 EXPERIMENTAL TERATOLOGY (Animals)

The previous sections have described congenital and early acquired forms of hearing loss induced by prenatal and perinatal damage to the fetus and developing embryo of viral, infectious, metabolic birth traumatic, and pharmacologic origin Although the first trimester is considered to be that developmental stage when the human ear is most susceptible to teratogenic agents, literature was cited suggesting that aural embryopathies may also occur in the second and third trimesters of embryogenesis. There is sound evidence to indicate that the stage in development at which an agent is applied or becomes active is an important factor in determining the reaction of the embryo (Wilson 1957) Wilson (1959) feels that the basic action of all teratogens appears to produce either cell death or alteration in the rate of cell growth Susceptibility to teratogenic agents subsides to zero rapidly after the 8th week it increases for noxious agents because of the rapid growth and development of the placenta and the corresponding rapidly increasing ability of diffusible substances to reach the fetal circulation (Litchfield, 1967)

The golden hamster exhibits certain reproduction features which make it a desirable animal for research in teratology These include the ease of obtaining timed matings, large litters, and a mere 16 day gestation period (Ferm 1965 1967). This gestation period is shorter than in any other commonly available laboratory mammal (Magalhaes et al 1962 a) Hamsters are also readily obtained clean inexpensive and easy to maintain and handle The increasing value of the hamster as an excellent animal model for experimental pathology and clinical medicine and its potential value for experimental and comparative biology is discussed in detail by Homburger & Bajusz (1970)

(a) Viral studies

Oxford (1967) studied the persistence of rubella virus in newborn and adult hamsters, mice, ferrets, adult rabbits, and guinea pigs after intranasal inoculation of the virus His findings produced evidence for multiplication of rubella virus in the lungs of the rabbit hamster guinea pig, and ferret persisting for

Middle ear

The development of the middle ear begins at 4 weeks, at the same time the otic placode of the inner ear is deepening to form the otocyst. At about the 5th week a small pouch from the pharynx appears and comes into relation with the first branchial arch. This pouch forms the middle ear and is soon divided into a tubular portion, which becomes the Eustachian tube and a saccular one, which becomes the tympanum. The primitive Eustachian tube closes again during the 3rd month but reopens during the 4th. The head of the malleus and body of the incus are laid down in the mesenchyme of the first arch, the manubrium of the malleus and long process of the incus in mesenchyme of the second arch. The stapes develops from the 2nd arch about the 7th week. They are cartilaginous models at 9 weeks, and completely ossified at 26 weeks (malleus), 32 weeks (incus), and 35 weeks (stapes). In the 23rd week ossification starts in the medial and lateral parts of the tegmen tympani and is complete near the end of the fetal period

(*b*) Hamster

The literature on the development of the ear in the golden hamster is meagre, as confirmed by Kittel (1966) and Magalhaes (1968) in comprehensive bibliographies on the golden hamster inclusive of years 1931–1965 and comprising a combined total of 8 016 citations No articles dealing solely with ear development were found, with the exception of the ossification of the hamster ear by Van Arsdel & Hilleman (1951). Information on the ear was excerpted from articles describing the complete development of the hamster which therefore lacked details and completeness regarding the membranous labyrinth and middle ear development. This system was briefly described by Boyer (1948, 1953 1968), but it covered only the prenatal period. No articles were found dealing with the continuing postnatal growth of the ear Boyer (1953) stated that obvious gaps remained that should be filled in after further investigations, but be presented a general chronology that should be of value in providing landmarks for more detailed study

The gestation period of the hamster is 16 days with implantation of the blastocyst occurring on the 6th day post coitum (Venable, 1946 Ward, 1948) Once embryogenesis begins, it proceeds very rapidly from 8 to 10 days post coitum, then it slows somewhat after 10 days (Boyer 1948) The 13-day hamster has reached a stage in development equivalent to that of a 16-day rat, 24-day pig, and 60-day human (Magalhaes & Briggs, 1962).

The following is a presentation of the known information on the development of the middle and inner ear of the hamster In comparison with the summary previously presented on the human, it is clear that many areas need completion and definition The results of this study will present a comparative developmental timetable of the human and hamster ear

Day of gestation

8 Auditory pits appear and quickly begin approaching closure. They are in contact medially with wall of myelencephalon and anteriorly with VIII nerve primordium

9 Otic vesicle closed. Ganglion of VIII nerve becoming distinct and is plastered against otic vesicle which is no longer in contact with either brain or body wall and is laterally compressed with slender endolymphatic duct extending dorsally from its medial aspect.

10 Otocyst constricted into upper vestibular pouch and lower more compressed, cochlear pouch with slight demarcation of the latter into saccule and more slender incipient cochlea

11 Semicircular canals starting to differentiate. Auditory ossicles are present in precartilage mesenchymal condensations (beginning of otic capsule). VIII cranial

dermal layer of the skin and neural ectoderm which forms the neural structures (Pearson *et al* 1967) The placode can be recognized in a 3 week embryo as a diffuse thickening in the hindbrain region (Bartelmez, 1922) In the 4th week the placode rapidly invaginates forming the otic pit which deepens and fuses its edges to form a closed vesicle the otocyst The otocyst becomes separated from the nervous system about the 4th or 5th week of intra uterine life and nerve fibers can be seen leading from the ganglion to different parts of the vesicle The otocyst partly divides into two parts which develop as the cochlea and vestibule The cochlea consists only of the cochlear duct and at 6 weeks this is represented by a short curved tube, extending to a single complete turn at 7 weeks (Streeter 1918) The scalae vestibuli and tympani are developed out of the surrounding mesenchyme at this stage The full 2 1/2 spiral turns of the cochlea are reached at 9–10 weeks

Differentiation of the epithelial lining of the cochlear du t is first apparent at about 8 weeks It begins in the basal turn followed by the middle and later the apical turns At 12 weeks, there is a well marked group of cells in the basal turn which already bear a resemblance to the future organ of Corti and the tectorial membrane is even more definitely laid down At about the same time the neural elements of the VIII cranial nerve and the acoustic spiral ganglion have linked the central nervous system with the sensory epithelium in the developing sense organ

At 4 months the cochlea is almost in its adult form the organ of Corti being so advanced in the basal turn that the outer and inner hair cells can be identified and the inner spiral sulcus is formed The tectorial membrane is free in its mature form and position By the development of the scalae vestibuli and tympani, Reissner's membrane and the basilar membrane are formed. The sensory end organ is well developed in the middle turn but still represented by a simple ridge of sensory cells in the apical turn. At 6 months the inner ear and sensory end organ have reached their normal development throughout the cochlea the fetus is viable and the cochlea appears ready to function Several studies have indeed demonstrated fetal responses to sound after the 20th week of gestation (Eisenberg 1970)

Osseous labyrinth

When the membranous otic labyrinth is nearly completed, the otic capsule chondrifies and then ossifies from 14 different ossification centers forming the petrous part of the temporal bone The first center is formed on the outer part of the capsule over the basal turn of the cochlear duct at 15 weeks The last ossification center occurs in the region of the fissula ante fenestram and the oval window which starts to ossify in the 22nd to 23rd week

Ossification centers develop in relation to the internal auditory meatus, the semicircular canals, and the terminal branches of the VIII nerve Ossification of each part of the internal ear does not begin until that portion of the internal ear has reached its adult size (Bast 1930)

The human petrous bone thus remains in an embryonal state throughout life because it must be ossified at birth This fact is dictated by the very purpose of the cochlea to serve as an acoustic analyzer If the dimensions of such an acoustic instrument were to grow during childhood the acoustic sensitivity would change daily until maturity Such continuous changes in frequency response would preclude any learning of auditory patterns and thus of language and all human thought The price of this phylogenetic evolution is the susceptibility of the human petrous bone to a variety of hereditary bone diseases, including otosclerosis that leads to conductive or mixed hearing loss. Otosclerosis afflicts only the petrous portion (not the squama and tympanic ring) of the human temporal bone not occurring in any other human bones nor in animals.

Middle ear

The development of the middle ear begins at 4 weeks, at the same time the otic placode of the inner ear is deepening to form the otocyst. At about the 5th week a small pouch from the pharynx appears and comes into relation with the first branchial arch. This pouch forms the middle ear and is soon divided into a tubular portion, which becomes the Eustachian tube, and a saccular one which becomes the tympanum. The primitive Eustachian tube closes again during the 3rd month but reopens during the 4th. The head of the malleus and body of the incus are laid down in the mesenchyme of the first arch, the manubrium of the malleus and long process of the incus in mesenchyme of the second arch. The stapes develops from the 2nd arch about the 7th week. They are cartilaginous models at 9 weeks, and completely ossified at 26 weeks (malleus), 32 weeks (incus), and 35 weeks (stapes). In the 23rd week ossification starts in the medial and lateral parts of the tegmen tympani and is complete near the end of the fetal period

(*b*) Hamster

The literature on the development of the ear in the golden hamster is meagre, as confirmed by Kittel (1966) and Magalhaes (1968) in comprehensive bibliographies on the golden hamster inclusive of years 1931–1965 and comprising a combined total of 8016 citations. No articles dealing solely with ear development were found, with the exception of the ossification of the hamster ear by Van Arsdel & Hilleman (1951). Information on the ear was excerpted from articles describing the complete development of the hamster which therefore lacked details and completeness regarding the membranous labyrinth and middle ear development. This system was briefly described by Boyer (1948, 1953, 1968), but it covered only the prenatal period. No articles were found dealing with the continuing postnatal growth of the ear Boyer (1953) stated that obvious gaps remained that should be filled in after further investigations, but he presented a general chronology that should be of value in providing landmarks for more detailed study

The gestation period of the hamster is 16 days with implantation of the blastocyst occurring on the 6th day post coitum (Venable 1946 Ward, 1948) Once embryogenesis begins, it proceeds very rapidly from 8 to 10 days post coitum, then it slows somewhat after 10 days (Boyer 1948) The 13-day hamster has reached a stage in development equivalent to that of a 16-day rat, 24-day pig, and 60-day human (Magalhaes & Briggs, 1962).

The following is a presentation of the known information on the development of the middle and inner ear of the hamster In comparison with the summary previously presented on the human, it is clear that many areas need completion and definition The results of this study will present a comparative developmental timetable of the human and hamster ear

Day of gestation

8 Auditory pits appear and quickly begin approaching closure They are in contact medially with wall of myelencephalon and anteriorly with VIII nerve primordium.

9 Otic vesicle closed. Ganglion of VIII nerve becoming distinct and is plastered against otic vesicle which is no longer in contact with either brain or body wall and is laterally compressed with slender endolymphatic duct extending dorsally from its medial aspect.

10 Otocyst constricted into upper vestibular pouch and lower more compressed, cochlear pouch with slight demarcation of the latter into saccule and more slender incipient cochlea.

11 Semicircular canals starting to differentiate. Auditory ossicles are present in precartilage mesenchymal condensations (beginning of otic capsule). VIII cranial

nerve is present in general pattern of adult condition

12 Malleus is beginning to show definitive shape semicircular canals are complete cartilaginous otic capsule is formed middle ear cavity enlarging

13 Ossification is beginning in petrous bone auditory ossicles laid down in cartilage

14 Calcareous deposits forming beginning of utricular otolith and saccular otolith

15 First ossification center in prearticular portion of the malleus

16 BIRTH

Postnatal
day

2 (18) First ossification centers of cochlea and incus.

3 (19) Head and anterior process of malleus nearly completely ossified Ossification begins in the incus.

4 (20) Facial and internal auditory meatus outlined First indication of ossification around lateral semicircular canal

5 (21) First ossification center of stapes oval window incompletely outlined and stylomastoid foramen completely outlined.

8 (24) First ossification centers of superior and posterior semicircular canals, beginning ossification of tympanic bullae first ossification center in Eustachian foramen Ossification reaches base of manubrium of malleus.

10 (26) First ossification center of basic mastoid process.

11 (27) Ossification complete around semicircular canals manubrium of malleus ossified paraflocculus outlined petrous bone ossified except for a portion of the lateral wall in the region of the semicircular canals.

12 (28) Incus ossified

14 (30) Bullae ossified First otoconia appear on maculae

15 (33) Petrous bone ossified.

17 (33) Head of stapes ossified incudo-stapedial articular surfaces ossified with the articulation between the incus and stapes remaining free

21 (37) Tympanic annulus ossified

III Materials and Methods

Animals

Golden hamsters (*Mesocricetus auratus*) were used exclusively for all experiments, including the males used for breeding purposes. Ages ranged from embryos of 11 (Fig. 1) 13 (Fig. 2), and 15 days gestation (Fig. 3), post natal ages 1 3, 6, 9 12, 15 and 20 days, to three adults. Hamsters were obtained from a commercial breeder who furnished reliable data on ages of all postnatal animals and mating times and gestation periods for the animals used for the experiments on embryos.

One of the unique features of the golden hamster is that its introduction into the laboratory is precisely known. Professor I. Aharoni, while on a zoological expedition in Syria, was fortunate to capture several live specimens from the environs of Aleppo. An adult female and a litter of young were unearthed from a deep burrow Eight of the litter were eventually brought to the Hebrew University of Jerusalem Unfortunately as a result of various mishaps, offspring were obtained from only one male and two females. The capture occurred during April 1930, and by August of that year the first litter of hamsters were born in captivity The animals were made available to Dr S. Adler a colleague of Professor Aharoni, who sent breeding stock to various parts of the world, some of which arrived in the United States in 1938 (Fulton, 1968 Robinson, 1968). From such a humble beginning, all the golden hamsters now in use as laboratory animals in Europe and America are considered to be descendants of the three litter mates of 1930 (Adler 1948). It is from this stock that all present domesticated strains have been developed (Walker 1964).

Equipment

The laboratory used for this study is equipped with a paraffin dispenser oven, American Optical Company (AO) rotary microtome, and various microdissecting instruments. Microscopes available are a Bausch & Lomb Stereo-Zoom series B microscope, AO Spencer dual observation Cycloptic steroscopic microscope series 58, and an AO Spencer dual observation trinocular PhaseStar microscope series 10, model P4 with photographic attachment for polaroid and 35 mm cameras.

Gross anatomy experiments

An adult hamster weighing 130 g was chloroformed, decapitated, and skinned, including the eyeballs. Corrosion of the head was accomplished by boiling in water until the soft tissues were dissolved, leaving two halves of the mandible with one incisor tooth in each, two temporal bones, and a partially disassembled skull. These were reassembled, glued to the head of an ordinary straight pin and mounted on a piece of cork (Fig. 4).

Two adults, one weighing 127.5 g and the other 123 g, were anesthetized with 0.3 cc sodium pentobarbital diluted with 0.7 cc distilled H_2O Perfusion fixation of tissues was done following the method of Koenig et al. (1945). A midline incision was made to expose the heart and a cannula inserted into the ascending aorta through an incision made in the left ventricle. An incision was made in the right atrium to provide an exit for the fluids. The cannula was in communication with two reservoir bottles attached to tygon tubing and a glass Y tube One bottle contained saline which was used first to wash

out blood, and the other 10% formalin which was used immediately after the saline Both animals died during the perfusion procedure and were decapitated Each head was cut through the midline and preserved separately in 10% formalin The specimens from one animal were grossly dissected and studied under the StereoZoom microscope The right side of the other animal was preserved with the brain intact (Fig 5) and the left side after removal of the brain (Fig. 6)

Embryological experiments

The procedure for obtaining embryos was the same for all specimens Each was chloroformed an abdominal midline incision made and the entire uterus removed Each embryonic sac was separated by cutting the umbilical cord. The uterine membrane was sectioned for removal of the embryo This was done macroscopically for the 13- and 15-day embryos and microscopically with a dissecting microscope for the 11-day embryos All embryos were immediately placed in 10% formalin

A hamster in her second breeding was mated on May 22, 1968 and the above described procedure was performed on June 2 the 11th day of gestation, with removal of 11 embryos ranging in size from 5–7 mm C–R length A hamster in her third breeding was mated on May 17 1968 and on May 30 the 13th day nine embryos ranging in size from 13–16 mm C–R length were removed The first breeding of a hamster 8 weeks of age was on March 6 1968 and on March 21 the 15th day thirteen embryos ranging from 25–30 mm C–R length were removed

Postnatal experiments

The procedure for obtaining postnatal specimens was the same for all ages. The young animals were chloroformed and decapitated. In less than a minute all skin was completely removed and the apex of the cranium shaved with a razor for faster penetration of formalin The specimens were immediately placed in formalin with a change of solution every 24 hours for 2 days. The ages of these hamsters were 1 3 6 9 12, 15 and 20 days, the 1 3 6 and 9 day hamsters being obtained from the same litter

Histological procedure

Techniques used for all phases of specimen preparation and staining were those described by Lillie (1965) Altmann (1966) Humason (1967) and Luna (1968) in the Manual of Histologic Staining Methods of the Armed Forces Institute of Pathology (1968) Specimens were fixed in 10% formalin for not less than 3 weeks. Decal (Scientific Products) was used for decalcification of all specimens, except the 11 and 13-day embryos for a period of time commensurate with the size of the specimen and amount of ossification Embryos and the 1 3 6 9 and 12 day postnatal specimens were embedded in paraffin and cut at 10 μ in the sagittal plane Fifteen

and 20-day specimens were embedded in celloidin and cut at 20 μ. The 15-day specimen was cut in the horizontal plane and the 20-day in the sagittal plane.

Serial sections of embryos were made. Three 11-day embryos were processed, two stained with the routine method for Hematoxylin and Eosin Y and the other with the silver method of Gordon & Sweets (1936). Two 13-day embryos were processed, one stained with H & E and the other with a combined Periodic Acid Schiff (PAS)-Silver method (Wilson, Ashburn & Williams, 1968). A 15-day embryo was serially sectioned with the even numbered slides stained with the PAS-Silver method and the odd numbered with H & E.

Every 8th, 9th, and 10th section of the post natal specimens 1, 3, 6, and 9 days embedded in paraffin was stained routinely with H & E. Two 12-day postnatal specimens were histologically processed and embedded in paraffin. One specimen had every 10th section stained with the PAS-Silver method with serial sections of one ear being made with the other specimen and stained with H & E. Every 5th section of the 15- and 20-day specimens was affixed to a slide and stained with H & E.

Microscopic study

Slides were initially studied under low power with the StereoZoom microscope which had magnifications of 7× to 30× and the dual observation Cycloptic microscope with magnifications of 7×, 10×, 15×, 20×, 25×, 30× and 40×. Detailed study was done with the dual observation trinocular PhaseStar microscope with magnifications of 40×, 100×, 200×, 500× oil immersion, and 1 000× oil immersion. Dark phase contrast was also utilized with 100× and 200× magnifications. Dark contrast reveals the histologic detail dark against a lighter background.

Photomicrography was done with the polaroid camera attachment on the AO Spencer PhaseStar microscope. All available magnifications were used for various details, but the 40× and 100× were predominantly used for photography in order to show overall orientation of the development of the ear in each specimen.

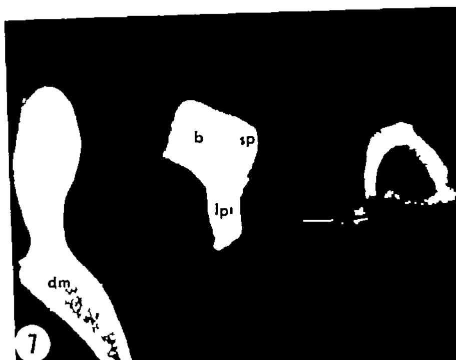
IV Results

1 GROSS ANATOMY

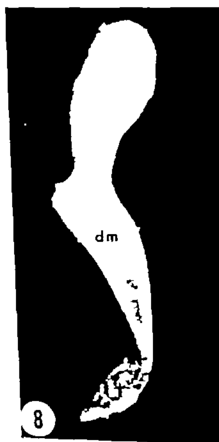
This gross description was made with the dissecting microscope utilizing low and high powers *Approximative measurements* were estimated with a double-pointed compass and ruler with 0 5 mm divisions

The pinna is triangular in shape covered with hair on the outside and contains numerous cartilaginous convolutions near its insertion on the temporal bone Cerumen is seen as a shining coat over the inside cavity The pinna *is freely movable* in the living animal and shows a clear Preyer reflex to sound Several adult male and female hamsters weighing between 120 and 140 g were observed demonstrating this reflex, and subsequently for this anatomical description

Following removal of the pinna, the external auditory cartilaginous canal opening is oval in shape and measures 3.5 mm × 2.5 mm Numerous short hairs are seen in the skin lining the canal The bony canal is very short, round, and measures 2 mm in diameter at the isthmus The tympanic annulus forms an incomplete circle measuring 3 mm The superior incision of Rivini is seen It is closed by a well-developed Shrapnell's membrane The umbo is easily seen in the midportion of the tympanic membrane The tympanic membrane has a vertical position with slight inclination in a forward-medial direction From this angle results a fairly deep anterior recess of the external meatus



All tissue and muscle was removed from the large tympanic bulla which was observed to be oval shaped The lateral bony wall was gently removed until the medial aspect of the tympanic cavity was seen The bulla is formed by very thin bone that is transparent like oily paper and less than 0.25 mm thick The longer sagittal diameter of the bulla is 8 mm and the shorter transverse diameter is 4.5 mm The temporal bone is loosely connected to the base of the skull, separating readily by dissection as well as by boiling



Approximately in the center of the medial tympanic wall is the promontory a round protruding mound The tympanic ostium of the Eustachian tube opens midway between the anterior pole of the bulla and the promontory Immediately in front of the promontory the apex of the cochlea can be seen The petrous bone is so thin at this point that a coil of the cochlea, presumably the apical turn, can be seen shining through it As expected the coiling runs clockwise in the left ear counterclockwise in the right Posterior to the promontory are seen the oval window superiorly and the round window inferiorly Both windows are less than 1 mm in their largest diameter and they are recessed within very deep niches The oval window niche contains the entire height of the stapes The two stapedial crura are in a line parallel to the long axis of the bulla i e the posterior crus is elevated from the horizontal line at an estimated angle of 15–20 degrees. The stapes is

Fig. 11. Middle and inner ear. 13th day of gestation. ×60.

freely mobile moving inward and outward when one gently touches the capitulum with a needle

Through the obturator foramen of the stapes runs the typically persistent stapedial artery not visible to the unaided eye but almost filling the space. It crosses the stapes at a right angle and therefore courses from inferior–posterior in a direction upward and forward at an angle of 65–70 degrees from the horizontal line The bony canal of the stapedial artery which appears as a ridge over the promontory has an outside width of 1 mm In one specimen this canal is dehiscent just in front of the round window This artery runs in its own canal anterior and closely parallel to the facial nerve It enters the ventral aspect of the bulla, courses upward and forward and leaves the temporal bone near the internal auditory meatus, thus passing in the opposite direction to the efferent facial nerve

From the capitulum of the stapes extends the glistening tendon of the stapedius muscle in a posterior direction The muscle is fan shaped before it disappears inside the facial canal. No pyramidal eminence for the stapedius muscle is present The facial canal is bony but extremely thin its thickness being a fraction of the thin bone of the bulla The facial nerve is at least 1 mm in diameter and has the expected course beginning as the horizontal tympanic portion, then curving downward behind the oval and round windows, leaving the temporal bone at the stylomastoid foramen Posterior to the facial nerve is the *horizontal semicircular canal*, parallel to the curvature of the nerve and therefore inclined 30 degrees to the horizontal line

The stapes is less than 1 mm in height. The footplate is oval measuring less than 0.5 mm × 1 mm in diameter (Figs. 7 9) The incus is similar to the human form with its longest dimension being 1.5 mm It has a short process for its antral joint and a long process for the incudostapedial joint (Fig. 7) The malleus in the hamster varies from the human form in that its manubrium is composed of two parallel bones connected by a thin membrane, rather than of one solid rod as found in the human (Figs. 7 8) This double manubrium resembles the shape seen in rabbits. The entire malleus from capitulum to umbo measures 3 mm The lateral portion of the manubrium measures 2 mm and the medial portion slightly less than 2 mm The tensor tympani muscle courses in an open groove above the Eustachian tube Its tendon turns around a small cochleariform process, and inserts on a protuberance of the malleus neck.

Superior to the labyrinth is seen a large epilabyrinthine recess measuring approximately 2 mm in diameter It is lined by mucous membrane and no function can be deduced. The superior and medial walls are very thin, separating this air filled recess from the cranial cavity

The cochlea was opened and the scala tympani scala vestibuli cochlear duct Reissner's membrane and stria vascularis were seen with pigment being observed along the basilar membrane. The labyrinthine capsule was opened by scraping it with a scalpel and the semicircular ducts were seen in the expected positions. Finally the vestibule was opened, exposing the saccule anteriorly and the utricle posteriorly The acoustic nerve leaves through *the internal auditory meatus and enters the* brain stem

Study of the posterior aspect of the temporal bone revealed a large excavation posterior to the internal meatus. This recess measures 2 mm in diameter and contains the paraflocculus of the cerebellum a typical arrangement in rodents

Many other morphologic deviations from human anatomy were seen which may be worthy of special description but this was outside the scope of the present work

2 MICROSCOPIC ANATOMY

The following description will mention structures observed when making their *first* appearance Thereafter only those making de

Fig. 12. Middle ear and vestibular portion of the inner ear. 15th day of gestation. × 40.

Fig. 13. Manubrium of the malleus, chorda tympani nerve and tensor tympani muscle, 15th day of gestation. × 400.

Fig. 14. Osteoblast formation in preparation of ossification of the manubrium of the malleus and Meckel' cartilage, 15th day of gestation. × 200.

bone. The stapedius muscle has assumed its distinct fan-shaped form and is attached to the stapes. The tensor tympani muscle is composed of ery small bundle of myoblasts and has reached the level of attachment to the malleus (Fig. 13).

Inner ear (*Fig. 12*). The otic capsule is cartilaginous with the internal auditory canal

finite observable morphological changes will be discussed.

(a) Prenatal

11th day of gestation

Middle ear (*Fig 10*) Meckel s and Reichert s cartilages are still connected with the anlagen of the ossicles. The shape of the malleus, in cus and stapes is well defined in precartilage mesenchyme Mesenchymal condensations are forming the tympanic membrane in conjunc tion with the manubrium of the malleus an tero-lateral to which the ectodermal epi thelium has invaded the mesenchyme to form the meatal plate The stapedial artery is very small and lies next to the differentiating facial nerve and courses between the crura of the stapes. The chorda tympani nerve is repre sented by a small bundle of fibers which lie in the looser mesenchyme that fills the interval between the malleus and incus

Inner ear (*Fig 10*) Precartilage mesen chymal condensations are forming the otic capsule excepting one area that is forming the internal auditory meatus. One turn of the cochlea is present its capsule being formed of precartilage The epithelium of each cochlear duct has a thickened portion showing cellular differentiation which is destined to be the or gan of Corti Blood vessels, which are branches from the cochlear division of the internal auditory artery are numerous in the me senchyme which fills the area to be occupied later by the scalae vestibuli and tympani On one side toward the future modiolus some of these vessels become the blood supply of the stria vascularis Most of those in the rest of the mesenchyme appear to undergo degenera tion or are separated by such a great distance from each other as to become difficult to find The acoustic ramus of the VIII cranial nerve terminates in the proximity of the thickened portion of each cochlear duct The spiral ganglion cells are few in number and very immature The semicircular canals, saccule ampullae ductus reuniens, and endolymphatic duct are differentiating surrounded by pre cartilage mesenchyme.

13th day of gestation

Middle ear (*Fig 11*) The middle ear cavity has slightly enlarged and the meatal plate still persists The ossicles are distinctly outlined in dense precartilage mesenchyme differentiating to cartilage The pharyngeal pouch, which is continuous with the Eustachian tube is erod ing the mesenchyme which surrounds the ossicles. The manubrium of the malleus and body of the incus are still united with Meckel s cartilage The manubrium is observed as a narrow strip attached to the primordium of the tympanic membrane The tympanic mem brane has thickened stretched further and is attached to the developing tympanic annulus. The stapedial artery and facial nerve are de veloping as previously described.

Inner ear (*Fig 11*) The otic capsule is dif ferentiating from precartilage to cartilage The semicircular and cochlear ducts continue cellular differentiation The cells in the cochlear ducts begin secreting a substance that will form the tectorial membrane The mesenchyme on each side of the basal turn of the cochlear duct is beginning to break down to form the beginning of the perilymphatic system The canaliculus cochlearis is beginning to form from which the perilymphatic duct will be developed The VIII cranial nerve has divided into a superior and inferior portion Spiral ganglion cells have increased in number and maturity

15th day of gestation

Middle ear (*Fig 1?*) The ossicles are well formed in cartilage Osteoblasts are being formed from eroding cartilage in preparation of ossification between the manubrium of the malleus and Meckel s cartilage (Fig 14) Me senchyme is breaking down to form the synovial membrane between the malleus and incus. The tympanic membrane is attached to the tympanic annulus which is partially membrane

Fig. 12. Middle ear and vestibular portion of the inner ear 15th day of gestation. × 40.
Fig. 13. Manubrium of the malleus, chorda tympani nerve and tensor tympani muscle, 15th day of gestation. × 400.
Fig. 14. Osteoblast formation in preparation of ossification of the manubrium of the malleus and Meckel' cartilage, 15th day of gestation. × 200.

bone. The stapedius muscle has assumed its distinct fan-shaped form and is attached to the stapes. The tensor tympani muscle is composed of a very small bundle of myoblasts and has reached the level of attachment to the *malleus* (Fig. 13).

Inner ear (Fig. 12). The otic capsule is cartilaginous with the internal auditory canal

well hollowed out Four sections of the cochlear duct, presumably representing two turns of the cochlea (Fig 18) are differentiating with the organ of Corti demonstrating more advanced cellular differentiation (Fig 19) The tectorial membrane is beginning to show definitive shape Perilymphatic spaces around the semicircular canals are forming well with some connective tissue trabeculae Ampullae are undergoing cellular differentiation The crus commune joining the posterior and superior semicircular canals is evident. Maculae of the utricle and saccule show definite shape with cellular differentiation occurring The vestibule is clearly defined along with the oval window and ductus reuniens

(*b*) Postnatal

1 day

Middle ear (*Fig 15*) Meckel s cartilage is regressing The middle ear cavity contains a large amount of mesenchyme

Inner ear The basal turn of the cochlea is showing well defined structural development that is not present in the middle or apical turns (Fig 21) Two-and-one half turns are present (Fig 20) Reissner s membrane shows definite form with its attachment to the developing spiral limbus in the basal turn Sensory cells on the organ of Corti are beginning to rearrange in all turns of the cochlea but to a greater degree in the basal turn (Fig 21) to form the rods and tunnel of Corti The tectorial membrane still lies just above the cells and is attached to the spiral limbus in the basal turn and in the area in the middle and apical turns that will become the spiral limbus The scala vestibuli is not formed in the apical turn The amount of mesenchyme in the vestibular system seems to have reached maximum intensity (Fig 16) *Cristae ampullares* of the semicircular canals show increased cellular differentiation (Fig 17) The vas spiralis is showing further development. The expanded end of the endolymphatic duct is seen just lateral to the brain at *the lateral* recess of the fourth ventricle

3 days

Middle ear (*Fig 22*) Meckel s cartilage continues to regress Membrane bone occurs in the medial wall of the tympanic canal Ossification is progressing on the lateral side of the malleus and medial side of the incus with varying stages of osteoblast formation (Fig 24) The facial nerve canal is outlined in cartilage The tensor tympani muscle with its tendon is attached to the manubrium of the malleus The tendon of the tensor tympani muscle is chiefly formed by slightly condensed mesenchyme

Inner ear (*Fig 22*) The first ossification center in the otic capsule occurs The limbus spiralis is well formed in the basal turn of the cochlea and the cells on the organ of Corti are showing definite shape (Fig 25) The tectorial membrane has become increasingly free from the cells on the organ of Corti and shows recognizable form The ganglion cells of the VIII nerve have increased in number and maturity Cristae ampullares of the semicircular canals continue to show rapid neural development (Fig 23)

6 days

Middle ear (*Fig 26*) Those structures partially ossified are the body and short process of the incus, the capitulum of the malleus and the crura of the stapes. The Eustachian tube is seen surrounded by cartilage The tympanic membrane is laying down fibers with varying stages of development and the annulus tympanicus is well formed as membrane bone

Inner ear (*Fig 26*) The rods of Corti make their first discernible appearance as demonstrated by the rearrangement of hair cells with a very small open space in the area of the arcuate zone on the basilar membrane (Fig 28) The spiral ligament shows increased density The stria vascularis has not become very vascular The tectorial membrane is now freely extended from its attachment to the spiral limbus and has begun forming fibers The *semicircular canals have begun to ossify (Fig.* 27) Their perilymphatic spaces have a re

one row of inner hair cells show a few hair like processes and immature cellular development. Claudius Hensen's, outer phalangeal cells of Deiter and inner phalangeal cells are observed in similar immaturity (Fig 29) The tectorial membrane has become increasingly fibrillar Maculae of the utricle and saccule show immature cellular development with only a few hair like processes apparent. Cupulae of the semicircular canals show few hair processes with immaturity of the hair cells of the cristae (Fig. 30)

12 days

Middle ear Ossification has advanced to most of the manubrium of the malleus, the long crus of the incus is completely ossified, and the footplate of the stapes has begun ossifying. The facial nerve is not well covered by its canal which is about half ossified. The canal of the chorda tympani nerve is almost completely surrounded by a thin layer of bone The tympanic membrane is still immature Mesenchyme is rapidly breaking down in the middle ear cavity The meatal plate has become separated from the tympanic membrane

Inner ear The petrous bone is approximately 75% ossified. The spiral ligament is well developed in the basal and middle turns of the cochlea (Fig. 31) but not in the apical turn The tectorial membrane is much further developed and fibrillar in the basal turn. The *space of Nuel is present* and the rods and tunnel of Corti further developed. The VIII nerve fibers are more numerous and well developed from the spiral ganglion cells along the basilar membrane and slightly beyond

their exit from the internal auditory meatus. The semicircular canals are almost completely ossified. Cristae ampullares of the semicircular canals are well developed with neural structures nearing completion (Fig 32)

15 days

Middle ear The malleus and incus are ossified except for the malleoincudal joint which remains cartilaginous. The manubrium of the malleus consists of two parallel bones connected by a thin membrane (Figs. 7 8) The bulla and petrous bone are ossified Bone of the bulla is observed to be extremely thin Mesenchyme continues to be abundant in the middle ear cavity The stapedial artery is seen in the obturator foramen of the stapes (Fig 34)

Inner ear A thin layer of bone surrounds all turns of the cochlea. The basilar membrane is developing well with increased cellular density and nerve fibers. Spiral ganglion cells continue to increase in size and number but are still immature All neural structures, the space of Nuel inner and outer tunnel pillars, and rods of Corti are clearly defined The spiral ligament shows increased density and appears stronger Reissner's membrane and stria vascularis are well developed. Pigment cells, first seen in the stria vascularis, are seen in the organ of Corti Fibers of the VIII nerve have increased in the internal auditory meatus and medulla. The semicircular canals and the parafloccculus recess are ossified Otoconia are seen in the maculae of the utricle and saccule with an increased number of hair cells observed The semicircular canals have well developed neural structures appearing ready to function (Fig 33)

20 days

Middle ear (Fig 35) Structures ossified are the facial canal tympanic annulus in its entire partial circle, the lateral surface of the stapes footplate and the head of the stapes and incudo-stapedial surfaces with a small amount

V Discussion

For an animal with such a short gestation period (16 days), implantation of the blastocyst is surprisingly slow not occurring until 6–7 days after fertilization, the same time as in the human with a gestation period of 270 days. Only 10 days remain for the fetal development *in utero* of the hamster As would be expected, hamsters are born in an embryonal state Newborn hamsters were observed to be able to stand and walk at 4 days of age although very limited with extreme incoordination. At 7 days they commence to eat small slivers of food pellets and have become much more active but are still fairly incoordinated. At 10 days of age they are able to reach the water bottle. Their eyes open at 16 days and coordination has improved. The hamsters are weaned at 22 days They continue to grow rapidly reaching maturity at 3? days, an age comparable to 13 years in the human The life span of the hamster is 2–3 years, a small fraction of the human life expectancy (70–75 years).

The anatomical relations of the hamster's middle and inner ear are relatively similar to the human A noteworthy difference is the persistence of the stapedial artery in the hamster which normally disappears during the third fetal month in human fetuses (House & Patterson, 1964) This rare abnormal persistence in humans has been associated with congenital sensorineural hearing loss, various other congenital abnormalities, skeletal abnormalities within the temporal bone, and tinnitus (Altmann, 1947 Kelemen, 1958 *a*, 1963). It presents a grave surgical hazard if encountered during operations on the ear The stapedial artery was consistently observed in the hamster at all ages described in this study

The manubrium of the hamster malleus is quite distinctive in its formation. Two small bones, one lateral and one medial, connected by a membrane form the malleus handle in contrast to one solid bone in the human. This arrangement is similar to that in the rabbit, but its significance is not known

The paraflocculus of the cerebellum is quite large and assumes an unusual position in the excavated center of the otic capsule. This space-saving development is typical for many rodents and apparently reflects their well-equilibrated agility

Developmental stages of the middle and inner ear of the hamster were compared to those of the human (Table I) by counting the hamster's embryonal stages in days and those of the human in weeks. This ratio of 1 7 reflects the astounding rapidity of ear development in the hamster In evaluating this comparison of the two developmental rates, a relationship of time in structural development could be deduced. The developmental times for both hamster and human are approximative for two reasons. The hamster produces a litter of 7–13 embryos, some of which may be more developed than others. In human embryos on the other hand, the precise developmental ages are but rarely known for certain because of the obvious limitations of available data.

Embryonal development begins at the same time in the hamster and human, 7 days after fertilization. The ear begins developing 1 day later in the hamster and 2 weeks later in the human. At this time the hamster ear develops rapidly in a period of acceleration to the 15th day of gestation which corresponds to a comparable developmental stage of the 15th gesta

of cartilage on the articulation between the incus and stapes. The tympanic membrane is well developed in an extremely large middle ear cavity that is relatively free of mesenchyme The stapedial artery remains persistent

Inner ear (*Fig 35*) The otic capsule is completely ossified The basilar membrane and the stria vascularis have thickened and matured with the tectorial membrane showing the same maturity The vas spiralis is seen just inferior to the basilar membrane Seen lateral to each turn of the cochlea is the cochlear ramus of the labyrinthine artery The development of the hair cells on the organ of Corti has advanced to a degree to suggest the possibility of response to sound. The bone around the semicircular canals, saccule, and utricle is very thin. The maculae of the saccule and utricle appear developed with numerous hair processes, nerve cells and fibers Cristae ampullares of the semicircular canals show mature development (Fig. 36). The perilymphatic spaces have become freer The paraflocculus is quite large occupying approximately 85% of the otic capsule (Fig 35) and appears mature with well differentiated Purkinje cells. The spiral ganglion cells and those of the ventral cochlear nucleus in the brainstem are more numerous and mature with many nerve fibers.

V Discussion

For an animal with such a short gestation period (16 days) implantation of the blastocyst is surprisingly slow not occurring until 6–7 days after fertilization, the same time as in the human with a gestation period of 270 days. Only 10 days remain for the fetal development in utero of the hamster. As would be expected, hamsters are born in an embryonal state. Newborn hamsters were observed to be able to stand and walk at 4 days of age although very limited with extreme incoordination. At 7 days they commence to eat small slivers of food pellets and have become much more active but are still fairly incoordinated. At 10 days of age they are able to reach the water bottle. Their eyes open at 16 days and coordination has improved. The hamsters are weaned at 22 days. They continue to grow rapidly reaching maturity at 32 days, an age comparable to 13 years in the human. The life span of the hamster is 2–3 years, a small fraction of the human life expectancy (70–75 years).

The anatomical relations of the hamster's middle and inner ear are relatively similar to the human. A noteworthy difference is the persistence of the stapedial artery in the hamster which normally disappears during the third fetal month in human fetuses (House & Patterson, 1964). This rare abnormal persistence in humans has been associated with congenital sensorineural hearing loss, various other congenital abnormalities, skeletal abnormalities within the temporal bone and tinnitus (Altmann, 1947; Kelemen, 1958 a 1963). It presents a grave surgical hazard if encountered during operations on the ear. The stapedial artery was consistently observed in the hamster at all ages described in this study.

The manubrium of the hamster malleus is quite distinctive in its formation. Two small bones, one lateral and one medial, connected by a membrane form the malleus handle in contrast to one solid bone in the human. This arrangement is similar to that in the rabbit, but its significance is not known.

The paraflocculus of the cerebellum is quite large and assumes an unusual position in the excavated center of the otic capsule. This space-saving development is typical for many rodents and apparently reflects their well-equilibrated agility.

Developmental stages of the middle and inner ear of the hamster were compared to those of the human (Table I) by counting the hamster's embryonal stages in days and those of the human in weeks. This ratio of 1 : 7 reflects the astounding rapidity of ear development in the hamster. In evaluating this comparison of the two developmental rates, a relationship of time in structural development could be deduced. The developmental times for both hamster and human are approximative for two reasons. The hamster produces a litter of 7–13 embryos, some of which may be more developed than others. In human embryos on the other hand, the precise developmental ages are but rarely known for certain because of the obvious limitations of available data.

Embryonal development begins at the same time in the hamster and human, 7 days after fertilization. The ear begins developing 1 day later in the hamster and 2 weeks later in the human. At this time the hamster ear develops rapidly in a period of acceleration to the 15th day of gestation which corresponds to a comparable developmental stage of the 15th gesta-

Table I *Development of the middle and inner ear*

Hamster days	Structure	Human, weeks
6–7	Blastocyst attaches to uterine mucosa	1
8	Otic placode middle ear begins development	3
9	Otocyst VIII nerve ganglion cells developing	4
10	Stapedial artery VIII nerve and chorda tympani begin developing VIII nerve fibers from otocyst precartilage mesenchyme forming otic capsule	5
11	3 semicircular ducts forming ossicles precartilage	6
	Saccule, utricle, maculae, crus commune, ductus reuniens, *scala tympani and cristae ampullares begin developing*	7
	One turn of cochlea precartilage otic capsule, organ of Corti begins developing; tympanic membrane, endolymphatic duct stapedius muscle begin developing	8
13	2½ turns of cochlea (Human) ossicles cartilaginous otic capsule cartilage scala vestibuli beginning of perilymphatic system, tympanic annulus and tectorial membrane begin developing	9
14	Otolithic membrane of maculae and cupulae of cristae, tensor tympani muscle	11
15	First ossification center of malleus tympanic annulus membrane bone; stapedial artery disappears in human 2 turns of cochlea (Hamster)	15
Birth–16		
1 (17)	2½ turns of cochlea (Hamster) Meckel's cartilage regressing	15
(18)	First ossification center of cochlea and incus	15
3 (19)	Malleus and incus ossifying; tympanic membrane and tympanic annulus well formed	16
6 (22)	Semicircular canals, stapes, and facial canal begin ossifying	18
9 (25)	Cells on the organ of Corti are recognizable and are differentiating to form the rods and tunnel of Corti stria vascularis is well developed	20
12 (28)	Meatal plate hollowed out	21
15 (31)	Malleus ossified semicircular canals ossified incus ossified (Human incus: 32 w.)	26
20 (36)	Membranous and osseous labyrinth developed middle ear developed Stapes ossified	28 35 36 *Birth*

tional week in the human (1 day 1 week ratio) The hamster is born on the 16th day in an embryonal state similar to the 15th gestational week in the human Development of the ear proceeds in a period of deceleration with the ear being essentially completed at 20 *days of age (5 weeks from fertilization)* corresponding with the 28th gestational week in the human

The development of the ear during the 11th day of gestation in the hamster shows remarkable rapidity Structures that take only 1 day to begin developing take 3 weeks in the human for similar structural development Ossification of the incus and stapes takes somewhat longer in the human as compared in time to the hamster resulting in a return to the 1 1 ratio observed After the acceleration period, this ratio is reached at the 15th day of gestation in the hamster and 15th week of gestation in the human Deceleration ensues with the final development taking 20 days in the hamster as compared to the initial acceleration period of 10 days in the hamster and 21 weeks in the human as compared to 15 weeks of initial accelerated development time At the time the stapes becomes ossified (36 days from fertilization in the hamster and 35 weeks in the human) a 1 1 ratio has once again emerged

Table II. *Development of the organ of Corti*

Hamster, days	Structure	Human, weeks
8	Otic placode	3
9	Otocyst	4
11	Cochlear duct	5
	One turn of cochlea, organ of Corti begins developing—inner ridge cells develop spiral limbus, outer ridge becomes organ of Corti	8
13	Tectorial membrane begins developing	9
15	2 turns of cochlea	9
Birth–16		
1 (17)	2½ turns of cochlea, Reissner's membrane	9
9 (25)	Differentiation of cells on organ of Corti occurring first in basal turn progressing to apical turn—outer ridge differentiates into inner and outer hair cells, Hensen's, pillar and supporting cells	20
20 (36)	Organ of Corti formed	23

The development of the organ of Corti (Table II) also shows interesting time relationships. The development of the sensory cells was observed to be faster in the hamster occurring in 13 days whereas the human equivalent in development occurs in a period of 18 weeks. However the 2 $^1/_2$ turns of the cochlea are developed sooner in the human than the hamster in a time relationship. By the 9th week the human has attained the full turns in a time period of only 1 week corresponding to a development period of 6 days in the hamster to attain 2 $^1/_2$ turns.

The hamster reaches maturity at 32 days after birth, compared to the human at around 680–740 weeks reflecting a marked delay. The life span of the hamster is generally 2–3 years corresponding to 70 years in the human, not a ratio of 7 times but 25–30 times. All stages of the hamster's life, embryogenesis, birth, maturation, and life span thus reflect the short time available for its life

Table I *Development of the middle and inner ear*

tional week in the human (1 day 1 week ratio) The hamster is born on the 16th day in an embryonal state similar to the 15th gestational week in the human Development of the ear proceeds in a period of deceleration with the ear being essentially completed at 20 days of age (5 weeks from fertilization) corresponding with the 28th gestational week in the human

The development of the ear during the 11th day of gestation in the hamster shows remarkable rapidity Structures that take only 1 day to begin developing take 3 weeks in the human for similar structural development Ossification of the incus and stapes takes somewhat longer in the human as compared in time to the hamster resulting in a return to the 1 1 ratio observed. After the acceleration period this ratio is reached at the 15th day of gestation in the hamster and 15th week of gestation in the human Deceleration ensues with the final development taking 20 days in the hamster as compared to the initial acceleration period of 10 days in the hamster and 21 weeks in the human as compared to 15 weeks of initial accelerated development time At the time the stapes becomes ossified (36 days from fertilization in the hamster and 35 weeks in the human) a 1 1 ratio has once again emerged

mentelles Versuchstier für das Studium der angeborenen Taubheit.

Diese Untersuchung zeigte, daß die Ohrentwicklung des Hamsters außerordentlich rasch vor sich geht, indem sie 20 Tage nach Geburt im Wesentlichen abgeschlossen ist. Eine Zeitspanne beschleunigten Wachstums zeigte sich zwischen den 8. und 15. Tagen der Gestation, welches der 3. bis 15. Woche der menschlichen Fötalzeit entspricht. Eben diese Zeitspanne der embryonalen Entwicklung ist dafür bekannt, daß sie für teratogene Schädigung besonders empfindlich ist, wozu auch Ohrschäden gehören. Eine weitere Periode von verlangsamter Entwicklung des Ohres ergab sich für die Gestationstage 15–20 beim Hamster im Vergleich zu einer gleichartigen Verlangsamung während der Schwangerschaftswochen 15–28 beim Menschen.

Der Hamster wird im embryonalen Zustand 16 Tage nach Empfängnis geboren, er erreicht sexuelle Reife 32 Tage nach Geburt, und hat eine Lebenserwartung von 2–3 Jahren. Das Dasein des Hamsters ist im Vergleiche zum Menschen noch mehr verkürzt als seine embryonale Entwicklung, welches im Laboratorium große Zeitersparnis bedeuten kann. Aus verschiedenen solchen Gründen erfreut sich der Hamster zunehmender Beliebtheit als ein gut brauchbares und praktisches Laboratoriumstier.

Résumé

Plusieurs agences professionelles ont rapporté le grand nombre de personnes qui souffrent à ce des pertes de l'ouïe de different degré. Ces agences soulignent aussi le grand besoin de recherches intensifiées en plusieurs champs afin de mieux clarifier la condition incapacitante que represente la sourdité. Une de cettes régions est le développement des models d'animal pour étudier les effets des substances tératogéniques qui peuvent insulter l'oreille pendant son développement de l'embryon. La pathologie de certaines autres formes de maladie de l'oreille qui attaquent après la naissance doit également être mieux clarifiée.

Ici est décrit pour la première fois le développement de l'oreille moyenne et intérieure chez le hamster. La séquence temporale des structures a été comparée avec celle chez l'homme. Une relation de 1 : 7 jours chez le hamster : vers semaines chez l'homme, est apparu pour comparaison. En précisant les details structurelles de l'oreille du hamster on a donc rencontré un animal expérimental de laboratoire pour l'étude de la surdité congénitale.

Les résultats de cette exploration ont montré que le développement de l'oreille chez le hamster procède très rapidement, étant essentiellement complété vingt jours après naissance. Une période de développement accéléré a été trouvée pendant les jours 8–15 de gestation, comparable aux semaines 3–15 de la gestation humaine. Pendant cette même période, le développement foetal est *très receptif* envers des substances tératogéniques *qui* peuvent causer des anomalies de l'oreille. Une période de décélération de *développement aural* s'est montrée pendant les jours 15–20 de gestation chez le hamster comparée avec les semaines 15–28 de gestation humaine.

Le hamster est né dans un état embryonnaire 16 jours après fertilisation. Il est mature et capable du reproduction à l'âge de 32 jours et il a une expectation de vie de 2–3 ans environ. Ainsi, son existence est même plus raccourci que sa vie embryonale, un fait très économique dans le laboratoire. Pour ces raisons variées, le hamster est devenu très populaire comme animal util et pratique dans le laboratoire.

Summary

An appallingly large number of humans suffering from varying degrees of hearing impairment have been reported by many agencies These groups stress the dire need for research in many areas to shed light on this disabling condition One of these areas is the development of animal models to study the effects of teratogenic agents damaging the ear during embryogenesis The pathology of other known types of ear disease after birth is also greatly needed

The development of the middle and inner ear of the golden hamster has been described for the first time The developmental timing of structures has been compared to the human A 1 7 time ratio days in the hamster to weeks in the human, was used for this comparison By establishing the structural details of the hamster ear an experimental laboratory animal for the study of congenital deafness has been developed

The results of this study have shown that the hamster's development of the ear proceeds extremely rapidly being essentially completed at 20 days after birth A period of accelerated development occurred from 8–15 days of gestation comparable to the 3rd to 15th weeks of human development This has been reported to be the period of fetal development most susceptible to teratogenic agents that cause ear anomalies. A period of deceleration in ear development occurred from the 15th day of gestation in the hamster and 15th week of gestation in the human until approximately 20 days of age in the hamster and 28 weeks gestation in the human.

The hamster is born in an embryonal state at 16 days after fertilization reaches maturity at 32 days of age and has a life span of 2–3 years. The hamster is enjoying increased popularity as a useful and practical laboratory animal

Zusammenfassung

Eine erhebliche Zahl von Menschen leiden an verschiedenen Graden von Hörverlust, wie von vielen offiziellen Körperschaften berichtet Diese Verwaltungsstellen betonen auch das ernste Verlangen nach mehr Forschung, um diese schweren Körperbehinderungen besser zu verstehen Eines dieser Forschungsgebiete betrifft die Entwicklung von Tiermodellen zum Studium der Auswirkungen von teratogenen Stoffen welche das Ohr während der Embryogenese schädigen können. Auch sollte die Pathologie anderer bekannter Arten von Ohrenkrankheit nach der Geburt besser erforscht werden

Hier ist zum ersten Male die Entwicklung des mittleren und inneren Ohres des Goldhamsters beschrieben Die zeitliche Entwicklungsfolge der Ohrstruktur des Hamsters wurde mit der menschlichen Ohrentwicklung verglichen Dabei ergab sich ein Zeitverhältnis von 1 7 was der Hamster in Tagen entwickelt braucht beim Menschen ebenso viele Wochen Aus diesem Nachweis der Entwicklung des Hamsterohres ergab sich ein experi

mentelles Versuchstier für das Studium der angeborenen Taubheit.

Diese Untersuchung zeigte, daß die Ohrentwicklung des Hamsters außerordentlich rasch vor sich geht, indem sie 20 Tage nach Geburt im Wesentlichen abgeschlossen ist. Eine Zeitspanne beschleunigten Wachstums zeigte sich zwischen den 8 und 15 Tagen der Gestation, welches der 3 bis 15 Woche der menschlichen Fötalzeit entspricht. Eben diese Zeitspanne der embryonalen Entwicklung ist dafür bekannt, daß sie für teratogene Schädigung besonders empfindlich ist, wozu auch Ohrschäden gehören. Eine weitere Periode von verlangsamter Entwicklung des Ohres ergab sich für die Gestationstage 15–20 beim Hamster im Vergleich zu einer gleichartigen Verlangsamung während der Schwangerschaftswochen 15–28 beim Menschen.

Der Hamster wird im embryonalen Zustand 16 Tage nach *Empfängnis* geboren, er erreicht sexuelle Reife 32 Tage nach Geburt, und hat eine Lebenserwartung von 2–3 Jahren. Das Dasein des Hamsters ist im Vergleiche zum Menschen noch mehr verkürzt als seine embryonale Entwicklung, welches im Laboratorium große Zeitersparnis bedeuten kann. Aus *verschiedenen solchen Gründen* erfreut sich der Hamster zunehmender Beliebtheit als ein gut brauchbares und praktisches Laboratoriumstier.

Résumé

Plusieurs agences professionelles ont rapporté le grand nombre de personnes qui souffrent avec des pertes de l'ouïe de different degré. Ces agences soulignent aussi le grand besoin de recherches intensifiées en plusieurs champs afin de mieux clarifier la condition incapacitante que represente la sourdité. Une de cettes régions est le développement des models d'animal pour *étudier* les *effets* des substances tératogéniques qui peuvent insulter l'oreille pendant son développement de l'embryon. La pathologie de certaines autres formes de maladie de l'oreille qui attaquent après la naissance doit également être mieux clarifiée.

Ici est décrit pour la première fois le développement de l'oreille moyenne et intérieure chez le hamster. La séquence temporale des structures a été comparée avec celle chez l'homme. *Une relation de* 1 : 7 *jours* chez *le* hamster vers semaines chez l'homme, est apparu pour comparaison. En précisant les détails structurelles de l'oreille du hamster on a donc rencontré un animal expérimental de laboratoire *pour l'étude* de la surdité congénitale.

Les résultats de cette exploration ont montré *que le développement de l'oreille* chez le hamster procède très rapidement, étant essentiellement complété vingt jours après naissance. Une période de développement accéléré a *été* trouvée pendant les jours 8–15 de gestation, comparable aux semaines 3–15 de la gestation humaine. Pendant cette même période le développement *foetal* est très receptif envers des substances tératogéniques qui peuvent causer des anomalies de l'oreille. Une période de décélération de développement aural s'est montrée pendant les jours 15–20 de gestation chez le hamster comparée avec les semaines 15–28 de gestation humaine.

Le hamster est né dans un état embryonnaire 16 jours après fertilisation. Il est mature et capable du reproduction à l'âge de 32 jours; et il a une expectation de vie de 2–3 ans environs. Ainsi, son existence est même plus raccourci *que sa vie embryonale*, un fait très économique dans le laboratoire. Pour ces raisons variées, le hamster est devenu très populaire comme animal util et pratique dans le laboratoire.

Acknowledgments

This study was undertaken as a doctoral dissertation in the Graduate School of the University of Mississippi School of Medicine, under the direction of Dr Godfrey E. Arnold (Professor of Otolaryngology) Dr Ira D Hogg (Professor Emeritus of Anatomy) Dr James W Ward (Chairman Department of Anatomy University of South Florida) Dr John F Jackson (Professor of Preventive Medicine) Dr Margaret B Batson (Associate Professor of Pediatrics) and Dr Jack W Crowell (Professor of Physiology) Mr John Dickson, Chief of Medical Illustrations did the photographic work Mrs Lorraine Turnage and Mrs Sally Jordan HT (ASCP) assisted with part of the histological work Mrs Susan Conerly typed the manuscript

Introduction

Our knowlege of the inner ear morphology in sensorineural hearing impairments in man is still largely deficient. In animals, the morphologic and electrophysiologic changes associated with cochlear lesions have been thoroughly investigated, but less so the course and the characteristic of the resulting hearing impairments. Furthermore one of the more extensively studied animals, with the most readily accessible cochlea, the guinea pig has stubbornly withheld its cooperation in hearing threshold determinations—until, in 1965 Anderson and Wedenberg described a new method for performing hearing threshold determinations in this animal. In model experiments they found that in hearing tests the Preyer reflex behaves similarly to the stapedius reflex in man.

An increasing number of sensorineural hearing impairments in man have been ascribed to genetic defects. It has even been possible to detect and define inherited subclinical stigmata in otherwise clinically normal-hearing carriers (Anderson & Wedenberg, 1968). In animals there are a large number of mutants with genetic deafness, and these, especially in rodents, often display behaviour al disorders which are conceivably due to concomitant vestibular dysfunction.

A strain of the waltzing guinea pig, originating from six waltzers received from the National Institutes of Health in 1961 has been bred and studied at the King Gustav V Research Institute. Genetic analysis has disclosed a dominant mode of inheritance with a recessive lethal effect (Ernstson, 1970) The vestibular function of the waltzers was severely impaired already at birth, and in the adult animals it progressively deteriorated to total loss of vestibular responses (Ernstson, 1971 a). The vestibular end-organs—the cristae and the maculae—showed progressive degeneration of the sensory cells, with a specific proteinoid rod shaped inclusion body in the type I hair cells. The nerve endings and the ganglion of Scarpa were normal in appearance (Ernstson 1971 a Ernstson et al., 1969 1970).

Progressive degeneration of the cochlear neuroepithelium, obvious already in the immediate post-natal period, eventually rendered the organ of Corti practically devoid of hair cells within 6–8 weeks of birth (Ernstson 1971). Degeneration of the supporting cells followed, and the spiral ganglion later displayed increasing depopulation of neurons. Other intra-cochlear structures were essentially normal in appearance. A special study of the cochlear vascular anatomy revealed no anomalies, even in the old waltzers (Axelsson & Ernstson, 1972, in press).

The aim of the present study was to elucidate the course and character of the hearing impairment and the cochlear hair-cell depopulation pattern in our strain of the waltzing guinea pig.

Material

This investigation was performed on 95 waltzing guinea pigs ranging in age from a few hours to about two months. A control group of 120 normal guinea pigs with a similar range of age was used.

Methods

The hearing measurements were carried out in a sound-proof chamber that effectively ex cluded environmental noise. Hearing thresh old determinations were performed by the method of Anderson and Wedenberg (1965) this is based on a peculiar characteristic of the guinea pig whereby on exposure to cold, it responds with periodic shivering of extreme regularity Previously conditioned animals re-act to a perceived tone stimulus with aboli tion of the shivering or a decreased shiver rate For complete details of technique and equipment the reader is referred to the ori-ginal paper Attenuator steps of 10 dB were chosen for the hearing threshold determina tions the following test frequencies were used 125 250 and 500 Hz; 1 1 1/2, 2, 3 4 8 and 12 kHz.

For Preyer reflex measurements carried out concomitantly with audiometry a spotlight was focused on the pinnae and the reflex ob-served through a window in the sound proof chamber For all the reflex determinations the test frequencies used were 0 5 1 2 3 and 4 kHz, with attenuator steps of 5 dB Preyer reflex measurements in the immediate post natal period were performed in the animal's compartment with a compact mobile version of the apparatus described by Wedenberg (1963)

Simultaneous determinations of the middle ear muscles (MEM) reflex and the Preyer re-flex thresholds were carried out as follows. The tone stimulus from a sound transducer was fed through a tube secured in or tus of the animal. A two-pronged pr affixed to the opposite meatus, and th reflex was recorded by a standard pr (see Klockhoff & Anderson 1959 Klo 1961 Anderson 1969) A spotlight pinnae facilitated observation of the reflex through a window in the soun chamber

A hair-cell population survey was m the following manner The cochlea fixed in osmium tetroxide solution an bedded in Epon according to standar tron microscopic practice (see Ernstson 1969) The specimens were cut in two th the modiolar axis. Semicircular piece taining the respective parts of the org Corti were excised and affixed systema on a slide. In this way durable and handled surface specimens of almos whole organ of Corti were obtained. specimens were examined under a phas trast microscope, and cochleograms wer duced as described by Engström et al. (I From these, averaged cochleograms wer structed. For each row of hair cells co tive groups of 10 cells were counted. Th sence of at least 6 cells was marked i averaged cochleogram as a filled circle presence of at least 5 hair cells was mark an open circle. The original cochleogram shown in appendices here, a filled circl notes a missing hair cell, and an open c a present hair cell.

NORMAL GUINEA PIGS

The normal threshold of hearing was estab-lished with 30 adult normal guinea pigs. The range and median values are given in Fig No attempt was made to determine thres levels below 0.0002 dyn/cm² the lowest te

level was zero dB. The median threshold of hearing corresponded remarkably closely to that found in man for a free-field presentation (ISO R 226). For use as a reference in further audiometry modal values were chosen (Table I), and in the following audiograms these values constitute the zero level.

The Preyer reflex thresholds were determined concomitantly in the 30 normal guinea pigs, the range and the median values are shown in Fig. 1. In the following audiograms the normal range is given (shaded area).

By very early conditioning of newborn guinea pigs it was possible to perform reliable hearing threshold determinations during the first week of life—earliest on the third day. Four normal guinea pigs were subjected to early audiometry and re-examined repeatedly. Not until about 10 days post partum were normal hearing threshold levels attained. An example is shown in Fig. 2. The Preyer reflex levels were within the normal range throughout the post-natal period.

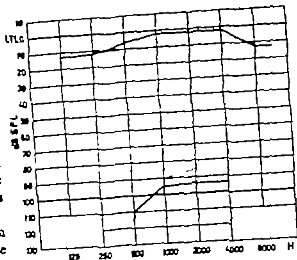

Fig. 1. Normal threshold of hearing for 30 adult guinea pigs (above), and normal Preyer reflex threshold (below). SPL values. Shaded area, total range; continuous line joins the median values for each frequency. *LTL*, lowest tested level.

WALTZING GUINEA PIGS

Twenty-four waltzing guinea pigs were conditioned for determinations of the threshold of hearing. An endeavour was made to obtain hearing thresholds as early as possible and to follow the development daily. Reliable hearing thresholds were recorded in 13 waltzers during the first week of life. Initially the thresholds were at the same level as, or slightly below that for the normals of similar age. Five of these waltzers showed a gradual improvement in hearing acuity and eventually hearing thresholds within the normal range were recorded. However the Preyer reflex thresholds in the waltzers, unlike those in the normal animals, were above the normal range and remained so throughout the post natal period (Figs. 3 and 10).

The difference between the Preyer reflex threshold in newborn normal and waltzing guinea pigs was the subject of a supplementary study performed on 162 animals, 68 waltzers and 94 normals. The thresholds were determined in the first 3 days of life. The median values and the semi-interquartile ranges for the two groups are presented in Table II. The difference between the median values was at least 5 dB at all frequencies except 3 kHz. There was no overlapping of the semi-interquartile ranges apart from a

NORMAL GUINEA PIGS

The normal threshold of hearing was established with 30 adult normal guinea pigs. The range and median values are given in Fig. 1 No attempt was made to determine threshold levels below 0 0002 dyn/cm² the lowest tested

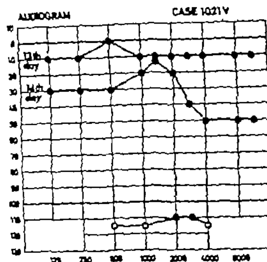

Fig. 4. First sudden impairment of hearing in waltzing guinea pig (no. 1021V). Audiograms obtained on 13th and 14th day of age. Note the reflex level, abnormally high but unchanged in spite of impairment of hearing threshold. Symbols, etc. as in Fig. 2.

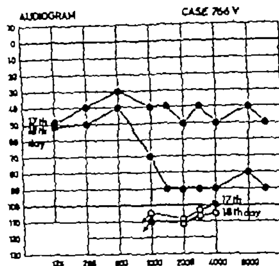

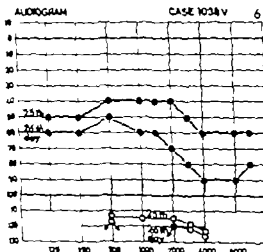

Fig. 5. Sudden hearing loss in middle intensity range in a waltzing guinea pig (no. 766V). Audiograms obtained on 17th and 18th day of age. Observe the much reduced gap between the hearing threshold and the reflex threshold (*recruitment*). Symbols, etc., as in Fig. 2.

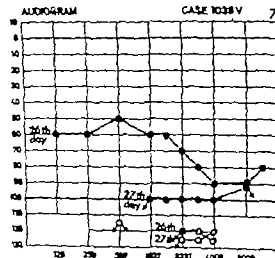

Fig. 6 and 7. Two steps of sudden hearing impairments without stable interval in waltzing guinea pig (no. 1038V). Audiograms obtained on 25th, 26th and 27th day of age. The figures illustrate how the high frequency range was first affected, and later the low frequency range. The relatively constant reflex levels reveal recruiting lesion. Symbols, etc., as in Fig. 2.

The Preyer reflex

The Preyer reflex threshold was always above the range for the normal guinea pigs, and it varied less than the level of hearing. Thus, even in those animals where the latter approached normal values the recorded reflex threshold was abnormally high. The subse

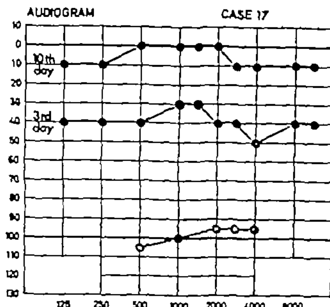

Fig 2 Audiograms obtained in a normal guinea pig (no. 17) on 3rd and 10th day of age showing post natal development of the hearing threshold. Filled circles, hearing threshold levels (free field determinations binaural hearing capacity) open circles, reflex threshold shaded area, normal range of the Preyer reflex threshold (see Fig. 1) Audiogram zero line represents normal threshold of hearing for guinea pigs

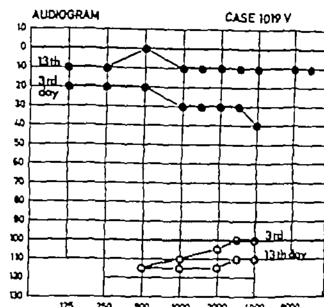

Fig 3 Audiograms obtained in a waltzing guinea pig (no. 1019V) on 3rd and 13th day of age, showing post natal maturation of hearing threshold. Note abnormally high reflex thresholds in spite of essentially normal threshold of hearing on 13th day Symbols, etc., as in Fig. 2

slight overlap at 3 kHz. The waltzing guinea pigs thus exhibited an elevated Preyer reflex threshold already in the immediate post natal period.

The subsequent course was followed in 7 waltzers until the hearing loss was total or the hearing threshold had dropped below 80 dB Of the further 17 waltzing guinea pigs, where this examination was begun but not completed some were sacrificed for morphologic examinations, others were discarded owing to sickness, and a few were lost because of too vigorous cooling during audiometry

In all the 24 waltzing guinea pigs the subsequent course was characterized by sudden stepwise, impairments of hearing acuity between which the hearing level was essentially stable These sudden impairments were initially confined to frequencies at and above 1 kHz, but later they appeared also in the low frequency region (Figs. 4 5 6 and 7). The stable intervals varied in duration from more than a week to nil. In a few animals a sudden loss of hearing was followed by a partial recovery of the previous threshold level lasting a few days. In some animals a gradual hearing loss of 10–20 dB was recorded for some days, but the sudden drops amounted to 30–50 dB or more No animal retained even residual hearing function beyond 42 days of age

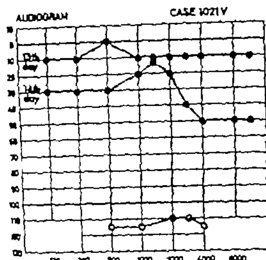

Fig. 4. First sudden impairment of hearing in a waltzing guinea pig (no. 1021V). Audiograms obtained on 13th and 14th day of age. Note the reflex level, abnormally high but unchanged in spite of impairment of hearing threshold. Symbols, etc., as in Fig. 2.

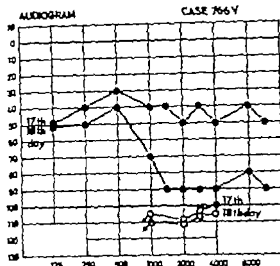

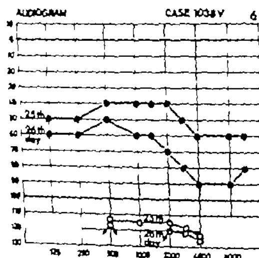

Fig. 5. Sudden hearing loss in middle intensity range in a waltzing guinea pig (no. 766V). Audiograms obtained on 17th and 18th day of age. Observe the much reduced gap between the hearing threshold and the reflex threshold (*recruitment*). Symbols, etc., as in Fig. 2.

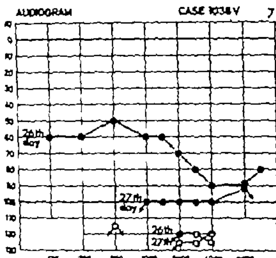

Fig. 6 and 7. Two steps of sudden hearing impairments without stable interval in a waltzing guinea pig (no. 1038V). Audiograms obtained on 25th, 26th and 27th day of age. The figures illustrate how the high frequency range was first affected, and later the low frequency range. The relatively constant reflex levels reveal a recruiting lesion. Symbols, etc., as in Fig. 2.

The Preyer reflex

The Preyer reflex threshold was always above the range for the normal guinea pigs, and it varied less than the level of hearing. Thus, even in those animals where the latter approached normal values the recorded reflex threshold was abnormally high. The subse-

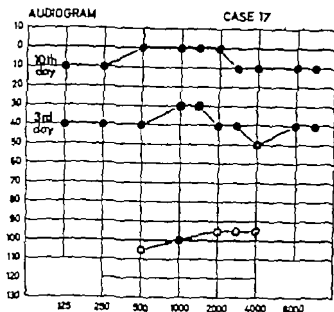

Fig Audiograms obtained in a normal guinea pig (no 17) on 3rd and 10th day of age showing post natal development of the hearing threshold. Fig 3 Audiograms obtained in a waltzing guinea pig (no 1019V) on 3rd and 13th day of age showing post natal maturation of hearing threshold. Note abnormally high reflex thresholds in spite of essentially normal threshold of hearing on 13th day. Symbols, etc., as in Fig. _

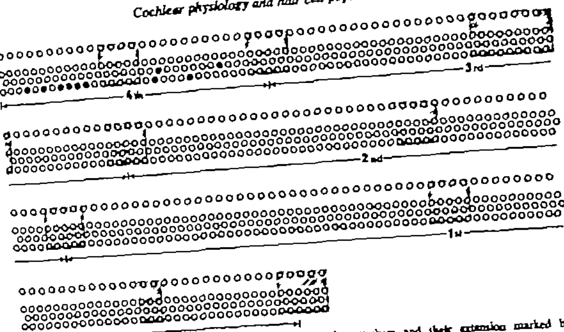
slight overlap at 3 kHz. The waltzing guinea pigs thus exhibited an elevated Preyer reflex threshold already in the immediate post natal period.



The subsequent course was followed in 7 waltzers until the hearing loss was total or the hearing threshold had dropped below 80 dB. Of the further 17 waltzing guinea pigs, where this examination was begun but not completed, some were sacrificed for morphologic examinations, others were discarded owing to sickness, and a few were lost because of too vigorous cooling during audiometry

In all the 24 waltzing guinea pigs the subsequent course was characterized by sudden, stepwise impairments of hearing acuity between which the hearing level was essentially stable. These sudden impairments were initially confined to frequencies at and above 1 kHz, but later they appeared also in the low frequency region (Figs. 4 5 6 and 7). The stable intervals varied in duration from more than a week to nil. In a few animals a sudden loss of hearing was followed by a partial recovery of the previous threshold level, lasting a few days. In some animals a gradual hearing loss of 10–20 dB was recorded for some days, but the sudden drops amounted to 30–50 dB or more. No animal retained even residual hearing function beyond 42 days of age.

A veraged cochleogram 1. Normal guinea pig (no. 1011 ala), prepared and cochleogram constructed as described (p. 6). Observe normally occurring slight hair-cell loss in the fourth turn. The turns are denoted by numbers and their extension marked by arrows. Shaded area represents approximate loss of hair cells from preparation. Cochleogram: see Appendix 1.

hair bundles. In the waltzing guinea pigs outer hair cells were missing also in the apical part, and to about the same extent. However in all these animals the other turns exhibited a greater or lesser hair-cell loss.

The mode of sensory cell degeneration in the waltzing guinea pigs has been described elsewhere (Ernstson, 1971 *b*). Abnormally configurated hair bundles were a common feature —at first on the inner hair cells and on the third row of the outer hair cells, and later in all the rows. The changes in hair-bundle configuration were most pronounced around the areas of maximum hair-cell loss. The degenerative changes in the sensory hairs are not indicated in the cochleograms, which, by definition, show only hair cells that are present or missing.

No 1013V illustrates the hair-cell population when the threshold of hearing had matured to within the normal range the reflex threshold was abnormally high (Fig. 10, averaged cochleogram 2, Appendix 2). The cochleogram revealed a random, in some areas quite extensive, hair cell loss, with a maximum in the basal part of the first turn. Another region where many hair cells were missing was the apical part of the second turn.

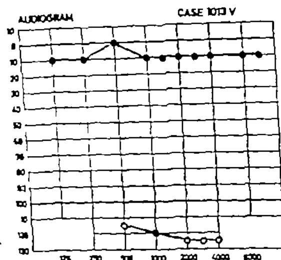

Fig. 10. Audiogram obtained immediately before sacrifice for hair-cell population survey in 14-day-old waltzing guinea pig (no. 1013V). Compare with averaged cochleogram 2 and Appendix 2. Symbols, etc., as in Fig. 2.

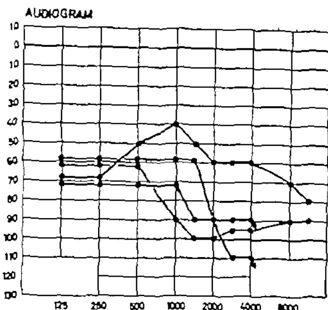

Fig 8 Audiograms showing hearing thresholds of 4 waltzing guinea pigs (nos. 43V 766V 1014V and 1019V) on the first day that the Preyer reflexes exceeded the audiometer capacity Thus, *an unelicitable Preyer reflex does not imply absence of hearing* Symbols, etc. as in Fig. 2.

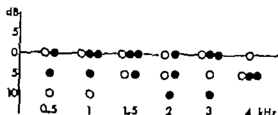

Fig 9 The middle-ear-muscles (MEM) reflex threshold level compared to the simultaneously determined Preyer reflex threshold level. For each point of measurement the MEM reflex was assigned the value of zero, and the corresponding level of the Preyer reflex threshold is shown (circles). Open circles: normal guinea pig filled circles. waltzing guinea pig.

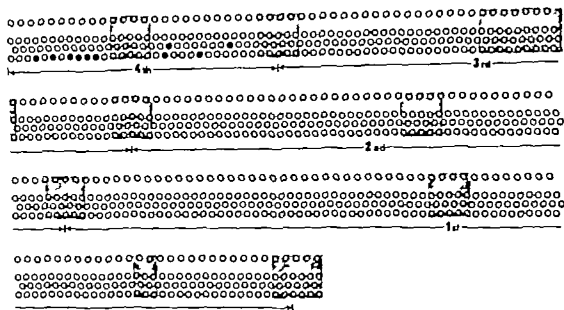
quent course was, in general, characterized by a constant, or almost constant, reflex level, although the hearing threshold deteriorated (Figs. 4 and 5) Eventually the reflex threshold rose above the maximum capacity of the audiometer

In all the waltzing guinea pigs the gap between the hearing and the reflex thresholds was reduced during the course of the deterioration in hearing—in extreme cases to only 10–15 dB (Fig. 5) The hearing impairment was therefore invariably characterized by *recruitment* (Anderson & Wedenberg 1965 Ernstson, 1972, in press)



The threshold of hearing in 4 waltzers on the first day that the Preyer reflex could not be elicited at any frequency is presented in figure 8 *Accordingly* an animal with a normal Preyer reflex threshold level may or may not have a hearing loss, whereas an animal with an elevated Preyer reflex threshold level or abolished reflex may still have normal, or at least reasonable hearing sensitivity *Thus the Preyer reflex is useless as a test of hearing acuity*

Further evidence of the usefulness of the Preyer reflex test as a recruitment test in differential diagnosis was obtained from simultaneous determinations of the MEM and Preyer reflexes. Five guinea pigs were used, 2 normal and 3 waltzers. The two reflex threshold levels were found to coincide within 5 dB for all but 4 out of 28 points of measurements in the 4 exceptional *determinations the* difference was 10 dB or 2 attenuator steps (Fig. 9) There was thus a close agreement in the levels of the MEM and Preyer reflexes.

Hair cell population

A hair cell population survey was performed in 5 animals—one normal and 4 waltzing. In one of the latter no 1038V both cochleae were examined the results are presented in averaged cochleograms 1–6 and Appendices 1–5

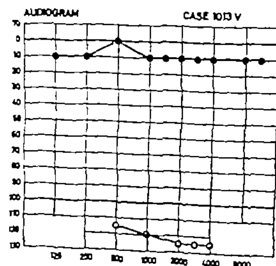
In the normal guinea pig (no 1011) some outer hair cells were missing in the fourth turn and in the apical part of the third (averaged cochleogram 1 and *Appendix 1*) The other hair cells were present and normal in *appearance* as was the configuration of the

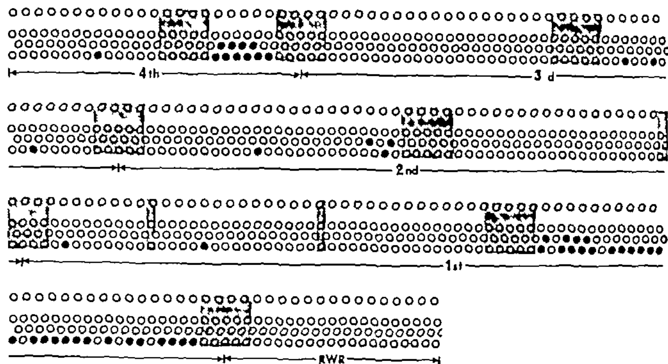
Averaged cochleogram 1. Normal guinea pig (no. 1011 sm), prepared and cochleogram constructed as described (p. 6). Observe normally occurring slight hair-cell loss in the fourth turn. The turns ar denoted by numbers and their extension marked by arrows. Shaded area represents approximative loss of hair cells *from preparation.* Cochleogram, see Appendix 1.

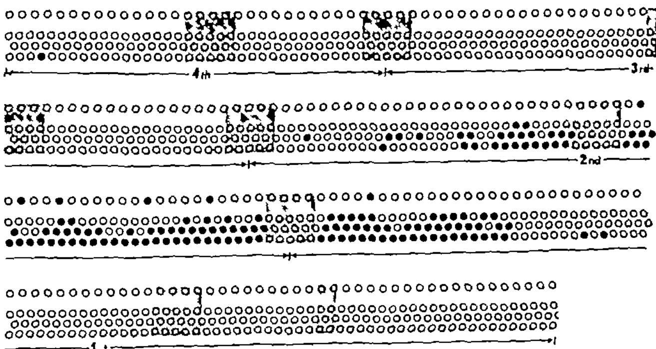
hair bundles. In the waltzing guinea pigs outer hair cells were missing also in the apical part, and to about the same extent. However in all these animals the other turns exhibited a greater or lesser hair-cell loss.

The mode of sensory cell degeneration in the waltzing guinea pigs has been described elsewhere (Ernstson, 1971 *b*). Abnormally configurated hair bundles were a common feature —at first on the inner hair cells and on the third row of the outer hair cells, and later in all the rows. The changes in hair-bundle configuration were most pronounced around the areas of maximum hair-cell loss. The degenerative changes in the sensory hairs are not indicated in the cochleograms, which, by definition, show only hair cells that are present or missing.

No 1013V illustrates the hair-cell population when the threshold of hearing had matured to within the *normal range* the reflex threshold was abnormally high (Fig. 10, averaged cochleogram 2, Appendix 2). The cochleogram revealed a random, in some areas quite extensive, hair cell loss, with a maximum in the basal part of the first turn. Another region where many hair cells were missing was the apical part of the second turn.







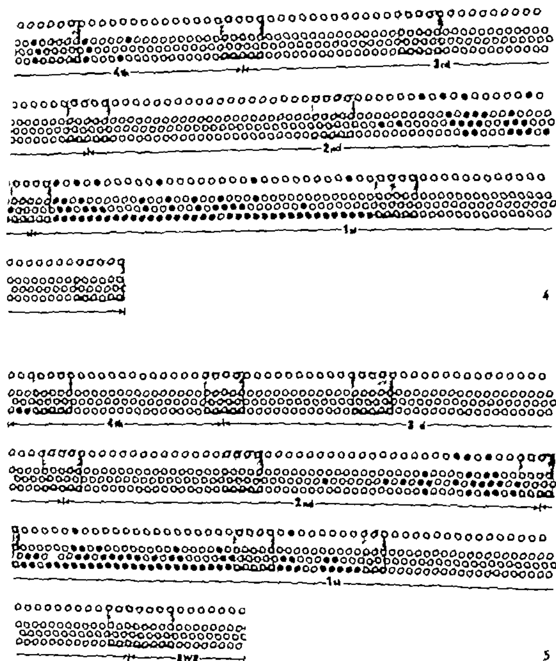


Fig. 10. Audiogram obtained immediately before sacrifice for hair-cell population survey in a 14-day-old waltzing guinea pig (no. 1013V). Compare with averaged cochleogram 2 and Appendix 2. Symbols, etc., as in Fig. 2.

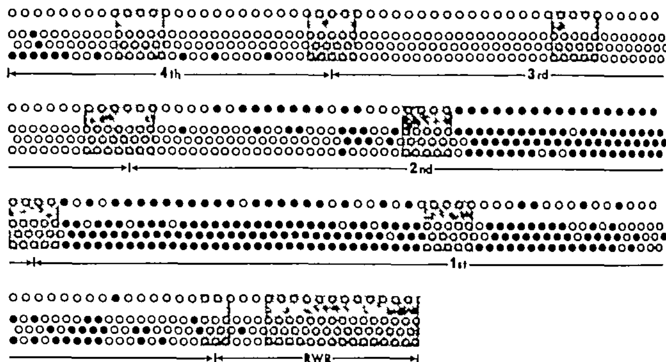
Averaged cochleogram 2 Immediately prior to preparation the animal (*no. 1013V dx*) *exhibited a normal* threshold of hearing but an elevated reflex threshold (Fig. 10). *Many third-row* outer hair cells missing in the basal part of 1st turn a random loss *of a few outer hair cells in the other turns. RWR*, round-window region Other markings as in averaged cochleogram 1 Cochleogram, see Appendix –



A eraged cochleogram 3 No. 12V sin. Hearing threshold at the 70–80 dB level immediately prior to preparation elevated reflex threshold and reduced gap between hearing and reflex thresholds (Fig. 11). A considerable number of outer hair cells lost at the transition of the 1st and 2nd turns a few inner hair cells also missing. Cochleogram see Appendix 3 *Markings as in a eraged cochleogram –*

Averaged cochleograms 4 and 5. In no. 1038V both organs of Corti were studied for comparison. Hearing function, see Fig. 12. Obvious elicitable reflex in spite of almost total deafness. The hair-cell loss in extent and localization are practically equal in the two ears, and similar to those in no. 12V. Few inner hair cells missing. Cochleogram of left ear: see Appendix 4. Markings as in averaged cochleogram 2.

Damage was most extensive in the third row of the outer hair cells, whereas very few inner hair cells were lost.

In no. 12V the reflex threshold level was comparable to that in the previous animal, but the hearing threshold was recorded at the

Averaged cochleogram 6 Here (no. 43V dx) the reflex was unelicitable 7 days prior to preparation the hearing threshold (Fig. 13) comparable to that in no. 1038V In the apical half of the 1st turn and the basal part of the 2nd turn few outer hair cells present: observe the corresponding inner hair-cell loss. Cochleogram, see Appendix 5 Markings as in averaged cochleogram 2.

70 dB level (Fig. 11 averaged cochleogram 3 and Appendix 3) There was a marked loss of outer hair cells in the first and second turns. In small areas all the outer hair cells were missing a few inner hair cells had also disappeared.

In no. 1038V the hearing threshold (Fig. 12) could be obtained for only 6 test frequencies

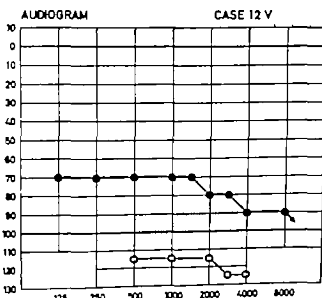


Fig. 11 Audiogram obtained immediately before sacrifice for hair-cell population survey in a 20-day-old *waltzing guinea pig (no. 12V).* Compare with averaged cochleogram 3 and Appendix 3 Symbols, etc., as in Fig. 2.

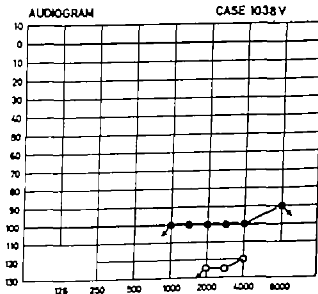

Fig. 12 Audiogram obtained immediately before sacrifice for hair-cell population survey in a 27-day-old waltzing guinea pig (no. 1038V). Compare with averaged cochleograms *4 & 5 and Appendix 4 Symbols*, etc., as in Fig. 2.

and the reflex threshold for only 3. There was a hair cell loss (Appendix 4) similar to that in the previous animal. The extent of the depopulation was practically the same in the two ears (averaged cochleograms 4 and 5).

No. 43V with a threshold of hearing comparable to that in no. 1038V showed an increased depopulation of hair cells in the organ of Corti (Fig. 13, averaged cochleogram 6, Appendix 5). Not only was there total loss of the outer hair cells in large areas but the corresponding inner hair cells were also missing. In this guinea pig the Preyer reflex was unelicitable already 7 days before sacrifice.

It should be observed that in all the waltzers, including nos. 1038V and 43V with their almost total loss of hearing, large parts of the cochleae were still populated with apparently viable hair cells. Even in no. 43V the third turn was essentially normal in this respect.

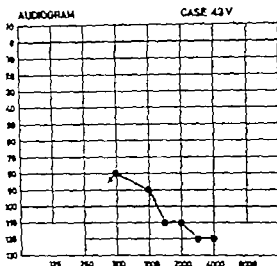

Fig. 13. Audiogram obtained immediately before sacrifice for hair-cell population survey in a 31-day-old waltzing guinea pig (no. 43V). Compare with averaged cochleogram 6 and Appendix 5. Symbols, etc., as in Fig. 2.

Discussion

The audiometric technique used in the guinea pigs was reasonably easy to perform and gave reproducible results. As the hearing threshold tests could be completed in less than half an hour they could be carried out almost hourly as previously shown (Ernstson, 1972, in press), and the method was therefore eminently suitable for evaluating even quite rapid changes in hearing acuity. Furthermore, once conditioned the animals retained their ability to respond appropriately for more than a year: supplementary conditioning was thus unnecessary.

Though there is now an abundance of studies of various aspects of the guinea-pig cochlea, remarkably little is known about this animal's normal threshold of hearing. In a pilot study Anderson and Wedenberg (1965) examined the hearing threshold in 2 guinea pigs. In the present study the normal hearing threshold was determined in 30 adult guinea pigs in order to provide a reference in further audiometric work. In the audiograms presented the SPL thresholds were converted so that the zero line actually represents the "normal threshold of hearing for guinea pigs". It should be observed that the lowest tested value was zero dB (re 0.0002 dyn/cm²). There was a distinct resemblance between the median hearing thresholds in guinea pigs and the normal hearing thresholds in man for a similar mode of tone presentation (free field, ISO R 226). As the hearing tests were performed in free field, the thresholds represent the binaural hearing capacity. No attempt was made to establish the total frequency range of hearing.

The range of the normal Preyer reflex thresholds was determined in the 30 normal adult guinea pigs. The median threshold level

was calculated and modal values were also chosen but in the audiograms the total range was used (shaded area) as this information proved more appropriate

Somewhat unexpected was the evidence of functional immaturity of hearing just after birth none of the 4 normal guinea pigs exhibited normal hearing thresholds in the first 10 days of life. The presence of a conductive impairment due to for instance middle ear fluid was ruled out by the normal reflex thresholds. Electron microscopic examination has disclosed no morphologic signs of post natal immaturity in the organ of Corti of the normal guinea pig (Ernstson, 1971 *b*) Vestibular tests in newborn and adult normal guinea pigs have yielded identical results (Ernstson 1971 *a*) Whether this progressive improvement in hearing acuity is indicative of a functional maturation process in the end-organ *per se* or whether it reflects an increasing adaptation of the animal to environmental stimuli remains an open question

The Preyer reflex has been widely accepted and used as a hearing test in the guinea pig. In his original investigation Preyer (1881) demonstrated the "maschinenmässigen Sicherheit of the reflex movements elicited by strong sound stimuli. However he also observed the ability of the newborn guinea pig to perceive the soft, rather low intensity voice of the mother "auch wenn diese nur ganz leise und abgebrochen schnurrt Preyer thus recognized the difference between supra and hearing threshold reactions. This difference has been largely overlooked, and the Preyer reflex has often been relied upon as the sole hearing test. The present investigation has shown that there is no parallel between the hearing threshold and the Preyer reflex threshold, and that *the Preyer reflex thus cannot be used as a test of hearing acuity* This affords an explanation of the discrepancies in the results of several earlier studies. On the other hand, the close agreement between the MEM and the Preyer *reflex thresholds in the* guinea pig justifies parallels with the stapedius reflex test in man. The accumulated knowledge from hearing tests in man, especially that relating to topical localization (recruitment) may therefore now be applied to the guinea pig.

It is well known that in many mutants of various species there is a gradual deterioration of the hearing acuity from birth. Even so determinations of the hearing threshold in animals with inherited cochlear lesions are scarce (see Anderson et al. 1968) Whereas the morphologic aspects of the inner ear degeneration has been extensively studied in many mutants (see Altmann, *1950* Deol, *1968*), the physiologic features such as the course and character of the hearing function impairment have received little attention

A study of the physiologic features was undertaken on our strain of waltzing guinea pigs. Even post natally the waltzers exhibited an elevated threshold of hearing and an abnormally high reflex threshold. In some of the animals the hearing acuity gradually matured to near normal, but the reflex thresholds remained above the normal range. The hearing usually stayed at a stable elevated level until later impairment

Whether the hearing acuity matured or not the subsequent course was characterized by sudden impairments in the hearing threshold separated by essentially stable intermissions. The impairments were initially confined to the higher frequencies, but later on the low frequency range was also affected. In some cases a partial recovery of the previous threshold level was noted. In some guinea pigs there was a slowly progressing but temporary elevation of the hearing threshold. The immediate cause of the sudden impairments is obscure and for obvious reasons cannot be ascertained by conventional morphologic methods.

The course of the hearing loss was invariably characterized by a reduced gap between the hearing and the reflex thresholds—that *is to say by recruitment* A topical diagnosis, in which the lesion was localized to the coch-

lea, was therefore performed and fully substantiated by the morphologic investigation (Ernstson 1971 *b*).

The results of the hair cell population survey was to some extent consistent with the audiograms—the more extensive the hair-cell loss the greater the hearing impairment. In contrast to the rather sharply demarcated cochlear hair cell damage caused by for example, ototoxic antibiotics (see Kohonen, 1965 Ostyn & Tyberghein, 1968, Stebbins et al., 1969), the depopulation pattern in the endogenous damage in the waltzing guinea pigs was considerably more diffuse. Furthermore, a large proportion of the sensory cells displayed changes of the hair-cell top and would not be expected to react to stimuli in the same manner as normal neuroepithelium, and hence there would hardly be any close consistency between the audiograms and the cochleograms. The hair-cell loss in the apical part of the cochlea is shown to be a regular feature (Stockwell et al. 1969).

The cyto-architectural division of the organ of Corti into outer and inner hair cells may reflect differences in properties, such as sensitivity The inner hair cells exhibit a morphologic resemblance to the phylogenetic older vestibular neuroepithelium (Wersäll & Flock, 1967). The animal in the present study whose Preyer reflex had been extinguished 7 days prior to sacrifice (no. 43V) had fewer inner hair cells over a wide area than the one (no 1038V) whose reflex could still be elicited, the impairment of the hearing threshold in these two animals was similar

Though not conclusively proved, it seems not unlikely that, being a more primitive and suprathreshold reaction, the Preyer reflex is initiated by the inner hair cells. The threshold of these would then be equal to the reflex threshold level. The outer rows of hair cells might respond to stimuli at the hearing threshold level and at increasing intensity until eventually the inner hair cells are stimulated and the reflex elicited.

Summary

The normal threshold of hearing for guinea pigs was established by the method evolved by Anderson & Wedenberg (1965). The course of the hearing loss was followed in a strain of the waltzing guinea pig with a dominant mode of inheritance of the anomaly In normal animals and some waltzers a post-natal maturation of hearing acuity was observed. The inherited hearing loss in the waltzers progressed by sudden steps separated by stable intervals of varying length. The high-frequency range was the first to be affected, later the low-frequency range. Throughout the period of the hearing loss there was a characteristic reduction of the gap between the hearing and the Preyer reflex thresholds, i.e. *recruitment*. The Preyer reflex threshold was abnormally high in the waltzers—even just after birth. The levels of the middle-ear-muscles reflex and the *Preyer reflex thresholds* were found to coincide in normal and in waltzing guinea pigs. It is concluded that whereas the Preyer reflex test does not disclose the hearing acuity it can be used as a topical test in differential diagnosis (recruitment). The parallels to the stapedius reflex test in man are obvious.

A hair-cell population study disclosed a progressive rather random loss of sensory cells, which was most pronounced in the first and later the second turns. The depopulation pattern was to some extent consistent with the audiograms. A tentative hypothesis is advanced regarding the role of the inner hair cells in eliciting the reflex.

was calculated and modal values were also chosen, but in the audiograms the total range was used (shaded area) as this information proved more appropriate

Somewhat unexpected was the evidence of functional immaturity of hearing just after birth none of the 4 normal guinea pigs ex hibited normal hearing thresholds in the first 10 days of life The presence of a conductive impairment due to for instance middle ear fluid, was ruled out by the normal reflex thresholds Electron microscopic examination has disclosed no morphologic signs of post natal immaturity in the organ of Corti of the normal guinea pig (Ernstson, 1971 *b*) Vestibular tests in newborn and adult normal guinea pigs have yielded identical results (Ernstson, 1971 *a*) Whether this progressive improvement in hearing acuity is indicative of a functional maturation process in the end-organ *per se* or whether it reflects an increasing adaptation of the animal to environmental stimuli remains an open question

The Preyer reflex has been widely accepted and used as a hearing test in the guinea pig In his original investigation Preyer (1881) demonstrated the "maschinenmässigen Sicher heit of the reflex movements elicited by strong sound stimuli However he also observed the ability of the newborn guinea pig to perceive the soft, rather low-intensity voice of the mother "auch wenn diese nur ganz leise und abgebrochen schnurrt Preyer thus recognized the difference between supra and hearing threshold reactions. This difference has been largely overlooked and the Preyer reflex has often been relied upon as the sole hearing test. The present investigation has shown that there is no parallel between the hearing threshold and the Preyer reflex threshold and that *the Preyer reflex thus cannot be used as a test of hearing acuity* This affords an explanation of the discrepancies in the results of several earlier studies. On the other hand the close agreement between the MEM and the Preyer reflex thresholds in the guinea pig justifies parallels with the stapedius reflex test in man The accumulated knowledge from hearing tests in man especially that relating to topical localization (recruit ment) may therefore now be applied to the guinea pig

It is well known that in many mutants of various species there is a gradual deterioration of the hearing acuity from birth. Even so determinations of the hearing threshold in animals with inherited cochlear lesions are scarce (see Anderson et al. 1968) Whereas the morphologic aspects of the inner ear de generation has been extensively studied in many mutants (see Altmann 1950 Deol 1968) the physiologic features such as the course and character of the hearing function impair ment have received little attention.

A study of the physiologic features was undertaken on our strain of waltzing guinea pigs. Even post natally the waltzers exhibited an elevated threshold of hearing and an abnormally high reflex threshold In some of the animals the hearing acuity gradually ma tured to near normal but the reflex thresholds remained above the normal range The hearing usually stayed at a stable elevated level until later impairment.

Whether the hearing acuity matured or not the subsequent course was characterized by sudden impairments in the hearing threshold separated by essentially stable intermissions. The impairments were initially confined to the higher frequencies, but later on the low fre quency range was also affected In some cases a partial recovery of the previous threshold level was noted In some guinea pigs there was a slowly progressing but temporary ele vation of the hearing threshold. The immedi ate cause of the sudden impairments is obscure, and for obvious reasons cannot be ascertained by conventional morphologic methods.

The course of the hearing loss was invari ably characterized by a reduced gap between the hearing and the reflex thresholds—that *is to say by recruitment A topical diagnosis,* in which the lesion was localized to the coch

lea, was therefore performed and fully substantiated by the morphologic investigation (Ernstson, 1971 *b*).

The results of the hair cell population survey was to some extent consistent with the audiograms—the more extensive the hair-cell loss the greater the hearing impairment. In contrast to the rather sharply demarcated cochlear hair cell damage caused by for example, ototoxic antibiotics (see Kohonen, 1965 Ostyn & Tyberghein, 1968 Stebbins et al 1969), the depopulation pattern in the endogenous damage in the waltzing guinea pigs was considerably more diffuse. Furthermore, a large proportion of the sensory cells displayed changes of the hair-cell top and would not be expected to react to stimuli in the same manner as normal neuroepithelium and hence there would hardly be any close consistency between the audiograms and the cochleograms. The hair-cell loss in the apical part of the cochlea is shown to be a regular feature (Stockwell et al., 1969).

The cyto-architectural division of the organ of Corti into outer and inner hair cells may reflect differences in properties, such as sensitivity. The inner hair cells exhibit a morphologic resemblance to the phylogenetic older vestibular neuroepithelium (Wersäll & Flock, 1967). The animal in the present study whose Preyer reflex had been extinguished 7 days prior to sacrifice (no 43V) had fewer inner hair cells over a wide area than the one (no. 1038V) whose reflex could still be elicited, the impairment of the hearing threshold in these two animals was similar

Though not conclusively proved, it seems not unlikely that, being a more primitive and suprathreshold reaction, the Preyer reflex is initiated by the inner hair cells. The threshold of these would then be equal to the reflex threshold level. The outer rows of hair cells might respond to stimuli at the hearing threshold level and at increasing intensity until eventually the inner hair cells are stimulated and the reflex elicited.

Summary

The normal threshold of hearing for guinea pigs was established by the method evolved by Anderson & Wedenberg (1965). The course of the hearing loss was followed in a strain of the waltzing guinea pig with a dominant mode of inheritance of the anomaly. In normal animals and some waltzers a post natal maturation of hearing acuity was observed. The inherited hearing loss in the waltzers progressed by sudden steps separated by stable intervals of varying length. The high-frequency range was the first to be affected, later the low-frequency range. Throughout the period of the hearing loss there was a characteristic reduction of the gap between the hearing and the Preyer reflex thresholds, i.e. *recruitment*. The Preyer reflex threshold was abnormally high in the waltzers—even just after birth. The levels of the middle-ear muscles reflex and the Preyer reflex thresholds were found to coincide in normal and in waltzing guinea pigs. It is concluded that whereas the Preyer reflex test does not disclose the hearing acuity it can be used as a topical test in differential diagnosis (recruitment). The parallels to the stapedius reflex test in man are obvious.

A hair-cell population study disclosed a progressive, rather random, loss of sensory cells, which was most pronounced in the first and later the second turns. The depopulation pattern was to some extent consistent with the audiograms. A tentative hypothesis is advanced regarding the role of the inner hair cells in eliciting the reflex.

Zusammenfassung

Die normale Hörschwelle für Meerschweinchen wurde mittels der Methode von Anderson und Wedenberg (1965) festgestellt. Der Verlauf des genetisch ausgelösten Hörverlustes wurde bei einem erblich dominanten Stamm waltzender Meerschweinchen untersucht. Bei normalen und einigen waltzenden Tieren wurde eine post natale Verbesserung des Hörvermögens gefunden. Der erbliche Hörverlust der waltzenden Tiere verschlimmerte sich sprungartig mit stabilen Intervallen bei unterschiedlicher Dauer. Anfangs wurde das hoch frequente, später auch das *tief frequente Gebiet getroffen*. Ganz charakteristisch während des Degenerationsvorganges war der verminderte Abstand zwischen der Hörschwelle und der Preyer Reflexschwelle was Recruitment zeigt. Die Preyer Reflexschwelle war bei den Waltzenden immer pathologisch erhöht, auch in der unmittelbaren post natalen Periode. Eine Übereinstimmung der Schwellen der Mittelohrmuskelreflexe und der Preyer Reflexe wurde an normalen und an waltzenden Tieren gezeigt. Es konnte klar gelegt werden, dass, obwohl der Preyer Reflex nicht zur quantitativen Bestimmung der Hörfunktion anwendbar ist, kann er doch für *differentialdiagnostische* Zwecke verwendet werden (Recruitment). Die Ähnlichkeit mit dem *Stapediusreflex beim Menschen ist auf*fallend.

Übersichtliche Untersuchungen an den Haarzellen des Cortischen Organs ergaben einem ziemlich variablen Verlust der Haarzellen, der sich von einer *Prädilektionsstelle* in den ersten und zweiten Schneckenwindungen mit zunehmendem Alter ausbreitete. Diese Vorgang war mit den Audiogrammen in gewisser Hinsicht übereinstimmend. Eine Hypothese über die Funktion der inneren Haarzellen wird präsentiert.

Acknowledgment

My sincere thanks are due to Henry Anderson, Assistant Professor in whose laboratory and under whose guidance and inspiring encouragement this work was carried out. Professor Bengt Barr, Professor Erik Wedenberg and Elis Pettersson, Engineer furnished invaluable support throughout the course of the work.

Introduction

The question of how efficiently man can localize a sound source in space received its first experimental answer using acoustical controls acceptable by modern standards in the study of Stevens & Newman (1936). Their results were recently popularized widely by Stevens & Warshofsky (1965). It appeared that one could not point to a sound source even in the frontal quadrant with less than a 3–4 average error at the better frequencies, while at other frequencies (including those at which the ear is most acute!) the error commonly reached 9–12 and at other quadrants was even greater But if we could not really do better than that, the race could hardly have survived and of course it was clear to the authors that information had existed for many decades on sound localization as a function separately of interaural differences in intensity phase and time-of-arrival on the basis of which one would predict a minimum audible angle (m.a.a.) of only a very few degrees at any frequency or azimuth.

This paradox was finally resolved in Stevens laboratory by Mills (1958), whose widely-cited paper revealed that the m.a.a. in the frontal quadrant (horizontal plane) was indeed of the order of 1–4 at any frequency and that the general shape of the curve of the m.a.a. s frequency was predictable from what was then known of interaural intensity and phase (Mills, 1960).

A few questions remain secondary to the major one solved by Mills classic study First of all, its importance makes a direct replication very much in order There is a perturbation in the data at 1.6 kHz such that the m.a.a. seems unaccountably poor in the data of Stevens & Newman a similar perturbation was an octave or more higher in frequency Why indeed should there be any frequency *effect* at all? Again, it appeared that when the sound sources came from a region about 60 off the midline, the m.a.a. deteriorated sharply But it is not our common experience that in daily life the errors at such angles are crippling.

Beyond checking Mills data, and perhaps exploring some seeming discrepancies, it would be important to know whether other types of directionality tasks would yield the same general precision of m.a.a. For example, Sandel et al. (1955) performed a directionality study using a different psychophysical procedure (an acoustical pointer") and their data have been recomputed by Mills (1960) to yield m.a.a. quite comparable to those of Mills; but only one azimuth was used. Generality of application would of course be improved if it could be shown that m.a.a. is relatively independent of method.

Going beyond the determination of m.a.a. at a selection of azimuths, elevations, and frequencies are broader questions. We wish to know what part of directionality can be accounted for by the physical characteristics of *S*'s head and pinnae, what aspect or aspects of interaural acoustic differences contribute to directionality and if more than one, we wish to know what portion is contributed by each aspect, whether intensity phase, time-of-arrival, etc.

The following studies were initiated in an attempt to redetermine normal human m.a.a. in the horizontal plane by several techniques, to throw some light on the physical conditions conducive to good directionality and to begin to assess the relative contributions of these.

Introduction

The question of how efficiently man can localize a sound source in space received its first experimental answer using acoustical controls acceptable by modern standards in the study of Stevens & Newman (1936). Their results were recently popularized widely by Stevens & Warshofsky (1965). It appeared that one could not point to a sound source even in the frontal quadrant with less than a 3–4 average error at the better frequencies, while at other frequencies (including those at which the ear is most acute!) the error commonly reached 9–12 and at other quadrants was even greater But if we could not really do better than that, the race could hardly have survived and of course it was clear to the authors that information had existed for many decades on sound localization as a function separately of interaural differences in intensity phase, and time-of-arrival on the basis of which one would predict a minimum audible angle (m.a.a.) of only a very *few* degrees at any frequency or azimuth.

This paradox was finally resolved in Stevens laboratory by Mills (1958) whose widely-cited paper revealed that the m.a.a. in the frontal quadrant (horizontal plane) was indeed of the order of 1–4 at any frequency and that the general shape of the curve of the m.a.a vs frequency was predictable from what was then known of interaural intensity and phase (Mills, 1960).

A few questions remain secondary to the major one solved by Mills classic study First of all, its importance makes a *direct replication* very much in order There is a perturbation in the data at 1 6 kHz such that the m.a.a. seems unaccountably poor in the data of Stevens & Newman a similar perturbation was an octave or more higher in frequency Why indeed should there be any frequency effect at all? Again, it appeared that when the sound sources came from a region about 60 off the midline, the m.a.a. deteriorated sharply But it is not our common experience that in daily life the errors at such angles are crippling.

Beyond checking Mills' data, and perhaps exploring some seeming discrepancies, it would be important to know whether other types of directionality tasks would yield the same general precision of m.a.a. For example, Sandel et al. (1955) performed a directionality study using a different psychophysical procedure (an acoustical pointer") and their data have been recomputed by Mills (1960) to yield m.a.a. quite comparable to those of Mills; but only one azimuth was used. Generality of application would of course be improved if it could be shown that m.a.a. is relatively independent of method.

Going beyond the determination of m.a.a. at a selection of azimuths, elevations, and frequencies are broader questions. We wish to know what part of directionality can be accounted for by the physical characteristics of *S*'s head and pinnae, what aspect or aspects of interaural acoustic differences contribute to directionality and if more than one, we wish to know what portion is contributed by each aspect, whether intensity phase, time of-arrival, etc.

The following studies were initiated in an attempt to redetermine normal human m.a.a. in the horizontal plane by several techniques, to throw some light on the physical conditions conducive to good directionality and to begin to assess the relative contributions of these.

...e two experiments, in view of the fact that many details of the apparatus and procedure differed, and that relatively few *Ss* were available for the many arduous sessions needed in the Method of Constants. We may take it as a generality then, that the normal human ear has an m.a.a. of about 1–2 through the audible range.

Mills' demonstration of a slight deterioration at 1.6 kHz was corroborated. His explanation, however must be re-exammed (see below) that 1 6 kHz is a frequency at which the interaural phase cue is becoming inoperative while the interaural intensity cue is not yet fully useful. It will be seen that the interaural intensity cue is fully sufficient to yield judgments of minimum sidedness, while the even more powerful interaural time cue is as available at 1.6 kHz as at any other frequency region.

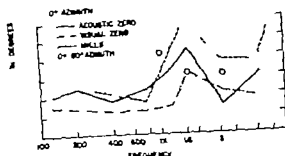

Fig. 1 Minimum audible angle as a function of frequency at 0° and 60° azimuth, for both an acoustic and a visual zero (including comparable data from Mills (1958) using an acoustic "zero").

Exper II Effect of Minimizing Head Movement

Although in Exper I the use of a bite board to fix the head, and a brief (1/4-sec) stimulus duration, reduced to what was thought a negligible effect of rotating the skull on the atlas, nevertheless some possibility existed that head movements may have played a role in the m.a.a. It seemed desirable to eliminate the possibility altogether

APPARATUS AND PROCEDURE

Ss, apparatus, and procedures were essentially the same as in Exper I, but the stimuli were presented to *S* by earphone and tape recorder The tape was prepared with the use of an immobile artificial head (see Fig. 2) inserted exactly a *S*' head in the anechoic chamber and picking up just such stimuli as in Exper I by way of high-fidelity equipment beginning with microphones in the position of the ear drums As before, *S* had to respond with L–R lateralization judgments.

The artificial head consisted of a balsa wood core carved by a sculptor with a layer of softish rubber about 1/4 to 1/2 inch thick. Pinnae of the same rubber transferred by a plaster of Paris technique from real heads were made, one from an adult with pinnae 2.5 inches in the vertical dimension, the other from a 6-year-old boy (the writer appreciates the courtesy of Todd N Harris in thus lending me his ears). Either pair could be pinned to the head over the meati and faired in with modelling clay to present an entirely normal appearance. The meati were simply wooden plugs 1.25 inches long with center-drilled 5/16-inch holes, the inner surface funnelled slightly to mate to Western Electric 640AA microphones (the courtesy of the Underwater Sound Laboratory in lending one of these, and the SubMedResLab the other is acknowledged). The outputs were led to Western Electro-Acoustic Lab preamplifiers filters, and VTVMs calibrated in SPL.

With both circuits carefully balanced for a single source at 0 azimuth, 2-channel recordings of typical 1/4-sec stimuli at 0.8 and 1.2 kHz were made on an Ampex PR 10-2 unit,

Exper I M A A with Acoustic "Zero"

SUBJECTS

One female (age 23) and three men (aged 32–44) were used all with normal hearing for the frequencies examined.

APPARATUS

A pair of 15 ft aluminum I-beams were supported one above the other in an anechoic chamber lined with 44-inch fiberglass wedges 32.5 ft from tip to tip. Each beam formed a railroad track marked off in inches to support an aluminum cart with nylon wheels, practically noiseless as it was pulled L or R along the rails by a variable speed reversible DC motor nylon pulleys, and steel thread system. On each cart was fixed a Jansen 15-inch triaxial loudspeaker and cabinet, the top cabinet upside down so that the axes of the speakers would be as close as physically possible namely 19 inches, to which S is relatively very insensitive

Conventional commercial oscillators, electronic switches and timers, filters, and attenuators controlled the frequencies, sound pressure levels (SPLs) and timing of the speaker outputs. A frequency meter and VTVM maintained frequency and intensity calibration A wave analyzer was used to examine the stimulus at certain times, but with the moderate SPLs (about 60 db SPL) and limited frequencies (0 125–8 kHz) employed distortion was never a problem.

PROCEDURE

S sat blindfolded in a comfortable chair fitted with a dental bite board, his interaural axis 10 ft from the middle of the rails. The bottom speaker was keyed on for a time (either 1/4 or 3 sec) always in S's median sagittal plane (0 azimuth) then after 1 sec the top speaker was keyed on for the same time. Rise-fall time was always 10 msec. S simply had to judge whether the second speaker seemed L or R of the first. Ten judgments were made by each S at each of a selection of distances (convertible by simple geometry to degrees azimuth) The distances were chosen at random within the range to blanket S's interval of uncertainty of directionality The 75%-correct distance was found graphically by plotting scores on probit paper An extraneous noise after every trial masked any sounds made by moving the top speaker to a new location between trials. Knowledge of trial results was not given except as specified below

RESULTS AND DISCUSSION

Table I shows the individual and mean m.a.a. when the stimulus duration was 1/4 sec. For all frequencies the m.a.a. was about 1–1.5 with the exception of 1 6 kHz where all Ss yielded their worst m a a. by roughly 1

A comparision of the mean data with those of Mills (1958) (see Fig 1) shows quite good agreement for this sort of judgment between

render more likely the efficiency of cumulative sampling.

RESULTS AND DISCUSSION

Table III gives the data for the three Ss. A detailed comparison with the germane figures in Table I reveals that no especial trend exists, except that the deterioration of m.a.a. at 1.6 kHz with the 1/4-sec duration is not seen with the 3-sec duration. It would seem that a fuller time sampling overcomes any disadvantage which this frequency may possess on the first quick look" at the stimulus.

Exper IV Effect of Azimuth

When Mills required his Ss to judge directionality with the first of two stimuli 60 off midline all m.a.a. deteriorated, but especially those in the region centered again on 1.6 kHz. We therefore repeated Exper III but at 30 azimuth for one S as well as at 60 for all Ss at 1 .5–3.2 kHz.

When the loudspeakers were set at 30 azimuth, it was immediately noted that even though the two loudspeakers were lined up on the same azimuth, the difference of a few degrees in the vertical dimension sometimes gave the impression that the second speaker (upper) was at a slightly different azimuth than the first speaker (lower) due to the geometry of the room and of its contents, however meager The upper loudspeaker was therefore set at 30° (or 60) and the lower moved L–R at the beginning of each experimental session to a new azimuth which

judgment being easy and precise for *S* it was in fact easy but imprecise. Table V shows the (to us) surprisingly large m.a.a. Note only that performance at 1.6 kHz was no better or worse than at other frequency regions.

The imprecision of the moving-source m.a.a. may be related to the fact that in the nature of the situation both stimulus and *S*'s head were moving, in which case *S* would be uncertain as to the effect of the movement of the source *per se*. With one *S*, indeed, at 1.6 kHz the head had to be stabilized by a bite board before real consistency appeared in the data.

Exper VI M.A.A with a Visual Zero

In daily life one of our commonest experiences is to coordinate the eyes with the ears. We seek to turn the head toward a source of sound of unknown directionality and form a congruence of meaning between the two senses. As the head is turned on the atlas so that the sound source is in the median sagittal plane, the interaural conditions are at maximum symmetry and the eyes also are symmetrically innervated and disposed. Using the direction of regard as a visual pointer then we felt *S* might be expected to say whether when his visual conditions were symmetrical, an asymmetry of the interaural conditions might be efficiently detected. Accordingly we put this hypothesis to test.

APPARATUS AND PROCEDURE

An acoustically transparent but visually opaque cloth was stretched on a wooden frame to obscure all apparatus. A vertical stripe (a length of white twine) was stretched also on the frame passing through the 0 azimuth. Experimenter positioned the speaker L or R of the midline at random, without acoustic or other cues, then alerted *S* to look fixedly at the stripe and listen for the ensuing 3-sec tone burst. Judgment L or R was called for

RESULTS AND DISCUSSION

Table VI shows that, contrary to our expectation, m.a.a. with only a visual zero is even

Table VI *Minimum audible angle in degrees for pure tones using a visual zero*

* Necessary to use a bite board to stabilize data.

seemed to S to be exactly that of the first sound source. Thereafter the second loud speaker was positioned around this new "Zero On successive settings the range of the new "Zero with respect to the true azimuth, was 12 inches L on one occasion at 1 25 kHz. Usually it was 2 inches or less. This asymmetric and unpredictable constant error was seldom found using the median sagittal plane, and was found somewhat more pronounced at the 60 azimuth than at the 30 However even at the 60 azimuth it never exceeded 12 inches L or R. For all sittings at 30 and 60 azimuth care was taken to control for this constant error

RESULTS AND DISCUSSION

A comparison of data for S JDH tested at 30 with his data at 0 (Table I) shows no tendency for m a.a to deteriorate with an off midline Zero Evidently with the constant error eliminated 30 azimuth is as good as 0° if not at absolute localization then at least at what may be termed vernier localization

The same conclusion arises from the data at 60 the data for Ss JDH and EBB may be compared with their data at 0 azimuth in Table I while the data for Ss. RLS and RLM may be compared with their data at 0° azimuth in Table II. If there is a trend for any S to perform better at 0 it is negligible in absolute amount

It seems likely that the striking deterioration of Mills Ss at 60 azimuth arose because a single sound source was moved physically from one position to another during the interval of silence between the two tones, and E was unable in this situation to measure and allow for a spatial constant error This conclusion accords with our common experience as we stand in a meadow and listen with eyes closed to an airplane moving across our right front quadrant we do not lose the distinctness of our impression of its direction as it moves from 0 and approaches 30 azimuth nor lose the impression altogether of where it is as it goes through the 60 azimuth

We therefore conclude that when the proper conditions are met, the human mechanism is capable of m a a. by this technique of the order of 1–2 at any azimuth and any frequency and with only a brief (1/4-sec or less) observation of the stimulus.

Exper V M A A with a Moving Stimulus

It occurred to us that an even better m a a. might be achieved if the sound source were not static, but continuously moving. In this case during the time of auditory observation S could continuously check and recheck his impression and as it were computerize a decision whether a sound source was moving L or R off the midline using as data the progressive interaural shifts in DI Dφ and or Dt as these were available

APPARATUS AND PROCEDURE

The DC motor for the upper track was arranged to move the loudspeaker at 2.5 /sec. As the speaker passed the midline moving either L or R, it tripped a microswitch which initiated the pure tone The azimuth over which the moving speaker was energized was controlled with a timer accurate to 1 msec A low level white noise masked any possible auditory cue to movement other than the pure tone S was blindfolded as usual and asked to judge whether the sound source moved L or R during the tonal interval

RESULTS AND DISCUSSION

Our first look at this problem was curtailed as it became apparent that far from this

ference between channels, seemed to come from about the 60 azimuth. This channel difference varied but was commonly about ±5 dB. We did not think it necessary to document this datum other than to have *S* indicate when the lateralization of the within-the head sensation seemed to be at about the same simulated azimuth as that of an actual sound source at 60 off midline. At this setting, *S* judged whether the second tone was L or R of the new phenomenological zero. Threshold DI was determined graphically as the 75% correct point.

RESULTS AND DISCUSSION

Table VII reveals that the threshold interaural DI at a simulated azimuth of 0 is usually of the order of 1 dB or less, and that changing the simulated azimuth to 60 has no deleterious effect whatever Evidently the deterioration of some of the m.a.a. data at 60° azimuth is no consequence of a systematic bias of stimulus intensity in a dichotic situation where interaural intensity is asymmetric.

Individual data show no trend across frequencies, and we conclude that the ears are as well adapted to utilize interaural DI information at low frequencies (where it does not exist in the usual free field situation below about 1 kHz) as at 6.4 kHz, where physical interaural DI may far exceed the amount needed to lateralize and localize to the extreme L or R.

Exper VIII The Effects of the Human Pinnae on the M A A at 0° Azimuth and 0° Elevation

The general nature of the effect of the whole head on the physical cues for interaural DI as a sound source is swept around the horizon has been clear for decades (see, e.g. Sivian & White 1933) We were interested in the relatively minor effects contributed by the pinna, nose cheekbone, etc. in providing a particular individual with DI cues of a minimal sort upon which m.a.a. judgments of the order of 1 could be based. We found, in fact, that these irregularities on the surface f the head do have or could possibly have significance in the real world for any *S*.

APPARATUS AND PROCEDURE

With one *S* an attempt was made to remove the pinna from utility by taping it closely to the head, and smearing cold cream liberally leaving only a slightly tapering funnel leading to the canal proper The same apparatus was used as in former experiments for the acoustic zero, visual zero and moving-loudspeaker m.a.a. always with a 3-sec observation interval. Unfortunately time was available only for observations at the 0 azimuth, In all probability other azimuths and elevations would have been more revealing.

more efficient than with an acoustic zero Tables I vs. VI reveal that visual zero was better in 20 of 28 possible comparisons of individual data at the seven common frequencies. The mean trends are seen in Fig. 1

Whether the visual zero task would have been more efficient than the acoustic zero had the visual task been limited to a 1/4-sec observation as in Table I is an unanswered question at the moment. Certainly 3 sec gave *S* plenty of time to oscillate the head through several cycles but from the slight, if any advantage of head movements seen in Exper III we would predict that the visual-zero task could be performed quite well with only a 1/4-sec observation interval.

It is obvious to us that the eyes and ears are coordinated down to within a fraction of a degree azimuth, and that the quickest and most efficient way to collect m a.a. data is to have *S* read off azimuth of a hidden sound source from a graduated arc, placed at about the same distance as the sound source.

It is noteworthy that for three of the four *Ss*, performance at 1 6 kHz, while still good, was worse than at any other frequency

Exper VII Interaural Differential Intensive Sensitivity

A broad look at how it is possible for m.a.a. as small as 1 or less to exist would include studies of (1) the physical cues available and (2) efficiency of human performance in utilizing these cues one at a time and in concert Among the questions in the latter category for which we felt more information was needed was that of interaural intensive discrimination (DI) Some data by Mills (1960) indicated that threshold interaural DI was just about the same in dB as the physical interaural intensity differences available to *S* when a sound source is 1–2 off midline thus the latter could serve as a localization cue in a free field However we wanted to know in addition whether some of the differences in m.a.a among our *Ss* could be explained by differences in their interaural DIs, and we further wished to know how the DI behaved when the phantom sound used as the basis for L–R judgments was placed not at simulated 0 azimuth, but displaced a simulated 60 off midcenter

APPARATUS AND PROCEDURE

A two-channel tape was prepared on an Ampex PR 10-2C recorder consisting of pairs of tones (rise–fall times of 10 msec) each 1/2 sec long separated by 0 1 sec silence. The first of each pair was always equal in intensity on the two channels, giving the sensation of a tone burst in the middle of the head when played diotically to a normal hearing *S* wearing ear phones. In case of some slight asymmetry of loudness with equal intensity *S* adjusted the gain of Channel II until midline localization for the first tone was achieved.

The second of each pair of tones was recorded on Channel I at one of a selection of intensity differences from that of the first pair either ±0 0 1 0 2 0 3 0 4 0 5 0 6 0 8 1 0 1 3 or 1.5 dB and of the opposite sign and the same intensity differences on Channel II Thus, dichotic differences of ±0 0 2, 0 4 0 6 0 8 1 0 1 2 1 6 2.0 2.6 or 3 0 dB were accomplished for the second tone. *S* simply had to judge at 40 dB sensation level whether the second of each pair was phenomenologically L or R of the first. Ear and frequency order were of course counterbalanced.

In a second procedure the gains in dB of Channels I and II were changed respectively up or down for each *S* until he reported that the "0 items, i.e. those with no built in dif

ference between channels, seemed to come from about the 60 azimuth. This channel difference varied but was commonly about ±5 dB. We did not think it necessary to document this datum other than to have *S* indicate when the lateralization of the within-the head sensation seemed to be at about the same simulated azimuth as that of an actual sound source at 60 off midline. At this setting, *S* judged whether the second tone was L or R of the new phenomenological zero Threshold DI was determined graphically as the 75% correct point.

RESULTS AND DISCUSSION

Table VII reveals that the threshold interaural DI at a simulated azimuth of 0 is usually of the order of 1 dB or less, and that changing the simulated azimuth to 60 has no deleterious effect whatever Evidently the deterioration of some of the m.a.a. data at 60 azimuth is no consequence of a systematic bias of stimulus intensity in a dichotic situation where interaural intensity is asymmetric.

RESULTS AND DISCUSSION

Table VII reveals that the threshold interaural DI at a simulated azimuth of 0° is usually of the order of 1 dB or less, and that changing the simulated azimuth to 60° has no deleterious effect whatever. Evidently the deterioration of some of the m.a.a. data at 60° azimuth is no consequence of a systematic bias of stimulus intensity in a dichotic situation where interaural intensity is asymmetric.

Individual data show no trend across frequencies, and we conclude that the ears are as well adapted to utilize interaural DI information at low frequencies (where it does not exist in the usual free field situation below about 1 kHz) as at 6.4 kHz, where physical interaural DI may far exceed the amount needed to lateralize and localize to the extreme L or R.

Exper. VIII. The Effects of the Human Pinnae on the M.A.A. at 0° Azimuth and 0° Elevation

The general nature of the effect of the whole head on the physical cues for interaural DI as a sound source is swept around the horizon has been clear for decades (see, e.g. Sivian & White, 1933). We were interested in the relatively minor effects contributed by the pinna, nose cheekbone etc. in providing a particular individual with DI cues of a minimal sort upon which m.a.a. judgments of the order of 1–2° could be based. We found, in fact, that these irregularities on the surface of the head do have or could possibly have significance in the real world for any S.

APPARATUS AND PROCEDURE

With one S an attempt was made to remove the pinna from utility by taping it closely to the head, and smearing cold cream liberally, leaving only a slightly tapering funnel leading to the canal proper. The same apparatus was used as in former experiments for the acoustic zero, visual zero, and moving-loudspeaker m.a.a., always with a 3-sec observation interval. Unfortunately time was available only for observations at the 0° azimuth in all probability other azimuths and elevations would have been more revealing.

Table VIII *Minimum audible angle at 0° azimuth by three methods with and without obliterating the features of the pinna with cold cream*

1 6	0.7	1 4	1.5	1 4	1 6	4 1
3.2	1 4	0.4	1 6	[illegible]	1 7	1 8
6.4	2.3	0 8	0.9	1.3	0.9	1 4

RESULTS AND DISCUSSION

Table VIII (see also Fig 3) reveals that obliteration of the distinctive features of the pinna had for this *S* no effect on m a.a. either for the acoustic zero task or the moving speaker task. There does, however seem to have been some contribution of the pinna to m a.a. at 0 8 and 1 6 kHz for the visual zero task Recall that with such a task (see again Table VI) this S did not show a relative break down at 1 6 kHz, although other *Ss* did. Now we see that even with this *S* when the pinna is reduced in effectiveness, m a.a. at 1 6 kHz is especially elevated as also its subharmonic 0 8 kHz. What this may tell us about the possible relation between wavelength at 1 6 kHz (about 8 inches) and the individual heads of our *Ss* will depend on what we can find out about individual differences of various sorts in this population At least we can gather from Table VIII that this S can use her pinnae to reduce certain ambiguities in L–R directionality when the half wavelength is of the order of the interaural distance.

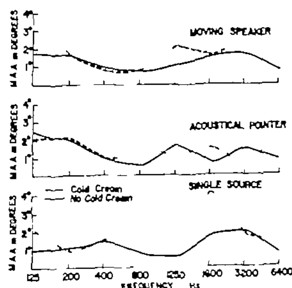

Fig 3 Minimum audible angle as a function of frequency at 0° azimuth by three procedures, each with or without the contribution of the pinnae. *S* EBB

Exper IX The Effects of the Sound Shadow of the Artificial Head and of its Pinnae Separately

Jahn & Vogelsang (1959) and Schirmer (1963) with real human heads, and Nordstrom (1962) with an artificial head among others, have recently made most detailed surveys of interaural physical DI as either azimuth and/or elevation is changed. These sets of data are for the case of the whole head including pinnae With the artificial head in Fig. 2 we were

able to document the sound shadow thrown by the whole head (1) including either of two sizes of pinna, or (2) with no pinnae at all. Obviously one can determine (3) the physical effects of the pinnae by subtracting (2) from (1).

APPARATUS AND PROCEDURE

The artificial head was mounted on a Bruel and Kjaer Model 3921 turntable, geared to a Model 2305 graphic level recorder fitted with polar coordinate paper and arranged so that the head looked directly at a triaxial speaker 8 ft distant. Either the head or the loudspeaker could be elevated so that the speaker was 30 above or below the level of the interaural axis. With this arrangement, two possibilities are offered. (1) the loudspeaker may be fixed at some relative azimuth and elevation and a recording from one eardrum taken with the frequency swept over 0 1–10 kHz, or (2) the frequency and elevation may be fixed and the head rotated so that the output from the eardrum represents the polar sound shadow at that frequency and elevation. We took the opportunity to do both.

The record for each frequency sweep, at any fixed geometry tells us what effect any particular frequency has on the soundshadow at that geometry as compared to the standard geometry of 0 azimuth and 0 elevation. Unfortunately we did not then have a vailable compensatory circuitry to present constant SPL at all frequencies to the head thus these data must first be corrected for the frequency response of the loudspeaker

It seemed to us that such information through the usable audio range could be abstracted by picking off the data for a selection of discrete frequencies from 0.5–8 kHz.

RESULTS AND DISCUSSION

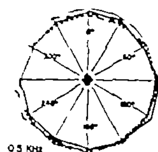

Fig. 4 A–C shows the data for four frequencies at each of the elevations (+30, 0, and −30) and at each of the 12 30 -step azimuths.

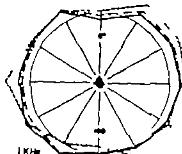
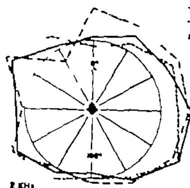


The points on these polar plots are not, however direct sound shadows. Each point represents a *difference* in intensity at the two ears, with the further conventions (1) that every datum to the R of the 0–180 meridian represents the case for the R ear and to the L for the L ear and (2) that the perfect circle drawn at an arbitrarily chosen radius represents the case where the SPLs at the two ear drums are equal. Thus in Fig. 4 B at 8 kHz, for the case of the head without pinnae (dotted line) at 60 azimuth, the interpretation is that for that particular frequency and geometry the R ear yields 11 dB more SPL than the L, while at −60 azimuth (+300) the L ear yields 12 dB more SPL than the R. Note carefully again that each point does not show the sound shadow cast at one ear alone, as in the usual display of such data, but the algebraic summation of the two shadows, one at each ear

The effects of pinnae of two sizes, can also be abstracted from Fig. 4 If we redraw the interaural DIs for the cases of the large and the small pinnae, each in terms of what they add or subtract from the interaural DI for the case of the head without pinnae, the effects of the latter are clear Fig. 5 A–C shows such data, where the perfect circle drawn at the arbitrarily chosen radius represents not interaural DI of 0, as in Fig. 4 but whatever the interaural DI was for the head with no pinnae at that azimuth and elevation of interest. Thus in Fig. 5 B at 8 kHz, for the case of the head fitted with the large pinnae at 60 azimuth, the interpretation is that for that particular frequency and geometry these pinnae reduce the interaural DI by 7 dB



One is struck, indeed, by the extent to which the pinnae of both sizes act rather to *reduce* the DI thrown by the head alone for all three elevations, twelve azimuths, and four frequencies represented, the pinnae reduce the interaural DI on 184 occasions out of 288, whereas the expectation would ordinarily be

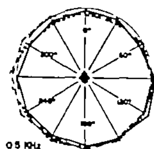
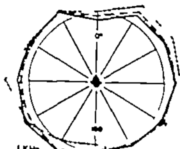
that the pinnae should act to *increase* the interaural DI cue and thus promote directionality. Considering the cases in Fig. 4 A–C, where the head alone throws quite different sound shadows at fairly close azimuths, it may be that the pinnae act to smooth out in some degree these saltatory conditions.

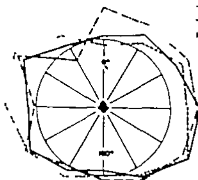
Figs. 4 and 5 show that for every head the



effect on interaural DI is unique for every frequency and geometry. One effect of this must be that for each of us the timbre of sounds will change with azimuth and/or elevation. Fig. 6 shows this graphically. Consider a white noise, with all frequencies of equal physical intensity yielding a certain sensation when the source is at 0° azimuth and 0° elevation. On the graphs of Fig. 6 this condition is presented by a horizontal line at 0 dB intensity at all frequencies. If now the sound source is changed to for example 60° azimuth and 30° elevation, Fig. 6 tells us that the timbre of the noise has a broad high-frequency boost for the ear nearer the sound source at all frequencies of 1–2 kHz and above, for the head either with or without the pinnae. And a comparison of curves for the 18 geometries in Fig. 6 A–C convinces one that the timbres of the white noise or of any complex sound will be quite different for each point in space, and for each set of pinnae. Thus through the intermediary of the sound shadow one could learn to associate the timbre of familiar sounds with their relative location.



Exper. X. Sound Shadow of the Human Head at ±5° Azimuth



APPARATUS AND PROCEDURE

With both meati fitted with small vaseline cotton plugs (to avoid canal resonances) and with probe microphones ending at the plane of the cavum concha, swept-frequency recordings were taken at both ears (S. JDH) of SPL with the sound source at 355°, 0° and 5° azimuth. A bite board helped stabilize geometry.

30 ELEVATION

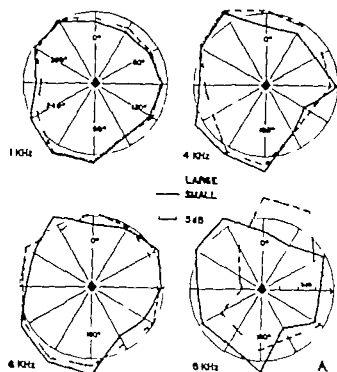
that the pinnae should act to *increase* the interaural DI cue and thus promote directionality Considering the cases in Fig 4 A–C, where the head alone throws quite different sound shadows at fairly close azimuths, it may be that the pinnae act to smooth out in some degree these saltatory conditions.

Figs. 4 and 5 show that for every head the



effect on interaural DI is unique for every frequency and geometry. One effect of this must be that for each of us the timbre of sounds will change with azimuth and/or elevation. Fig. 6 shows this graphically. Consider a white noise, with all frequencies of equal physical intensity yielding a certain sensation when the source is at 0° azimuth and 0° elevation. On the graphs of Fig. 6 this condition is presented by a horizontal line at 0 dB intensity at all frequencies. If now the sound source is changed to, for example, 60° azimuth and 30° elevation, Fig. 6 tells us that the timbre of the noise has a broad high-frequency boost for the ear nearer the sound source at all frequencies of 1–2 kHz and above, for the head either with or without the pinnae. And a comparison of curves for the 18 geometries in Fig. 6 A–C convinces one that the timbres of the white noise or of any complex sound will be quite different for each point in space, and for each set of pinnae. Thus through the intermediary of the sound shadow one could learn to associate the timbre of familiar sounds with their relative location.

Exper. X. Sound Shadow of the Human Head at ±5° Azimuth

APPARATUS AND PROCEDURE

With both meati fitted with small vaseline cotton plugs (to avoid canal resonances) and with probe microphones ending at the plane of the cavum concha, swept-frequency recordings were taken at both ears (S. JDH) of SPL with the sound source at 355°, 0° and 5° azimuth. A bite board helped stabilize geometry.

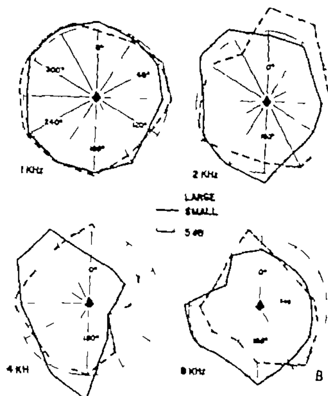


Fig 5 A–C. Abstracted from Fig. 4 A–C The effect of the pinnae alone on the sound shadow Note The perfect circle here represents the sound shadow if any thrown by the head alone

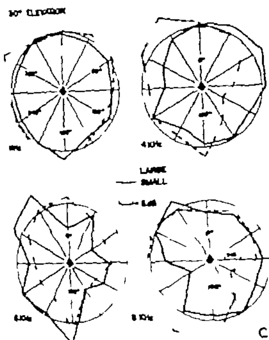
RESULTS AND DISCUSSION

Fig. 7 shows that at only 5 off midline there were interaural DIs in extent quite sufficient at most frequencies to support good localization on the basis of intensity alone.

Exper XI Minimum Audible Field at ±5 Azimuth

APPARATUS AND PROCEDURE



A closer look at the usefulness of physical DI cues in this azimuth region was had by asking *Ss* to take detailed monaural audiometric threshold tracings as the sound was swept from −5 to +5 azimuth A speed of 0 5 min/degree was arranged a frequency chosen (1 6 3 2 6 4 or 10 kHz) and *S* (with L ear plugged) traced his R ear Bekesy threshold as he sat blindfolded with a bite board facing the 0 azimuth. Control observations were also made at 30 60 and 90 azimuth.

On our Reger Bekesy audiometer not only may one vary the speed of frequency sweep, but also attenuation speed this was sometimes adjusted to that which gave the best indication of trends in available dB/degree

To satisfy ourselves that the technique gave reliable data for each *S* three tracings were collected for each frequency at each of the four main azimuths 0–90 a total of 48 tracings per *S*

RESULTS AND DISCUSSION

Fig 8 A–D shows representative data Fig. 8 C illustrates the test-retest consistency at 1 kHz with one *S* and 8 D at 6.4 kHz in another *S* Very commonly there was an indi

cation in the tracing itself of exactly when the sound source crossed the 0 azimuth, and in almost every tracing there are repeatable differences between the azimuths in the 10 range which amounted to 2+ dB/degree, that is, quite sufficient to account for discriminable azimuths a very few degrees apart. Thus physical cues for loudness would be enough to subserve the m.a.a. found in Fig. 1

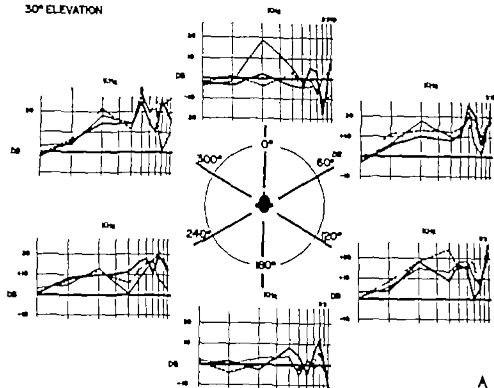
These observations apply especially to the region of the midline· but even at other azimuths there were differences across a 10° range which could subserve usable m.a.a.

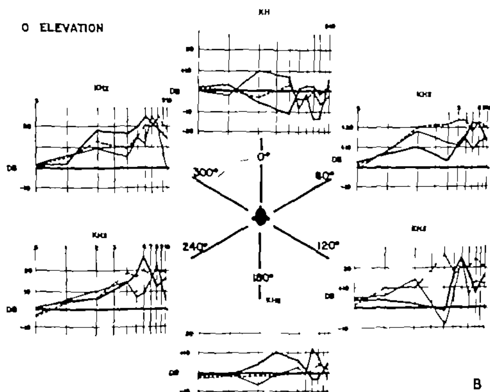
Exper XII M A A with Interaural DI as the Only Cue

In all experiments thus far in the free field, all possible physical cues were always present, so that it is impossible to decide which cues may be prepotent for or even used at all by the auditory mechanism Experimental ways were devised to isolate the cues of intensity and time separately The cue of phase could not be isolated in the free field in an unadmixed fashion, but it could at least be pre ented from obtruding by the choice of a fre quency 3 2 kHz, far above that known to be important for DØ under earphones. This would lea e DI and Dt as possible physical cues We looked first at DI in isolation.

APPARATUS AND PROCEDURE

S using a bite board was placed as usual 10 ft perpendicular from the center of the alu the loudspeaker could be moved and positioned L–R as needed. Behind the opaque screen the usual L–R placements were counterbalanced to determine m.a.a. at the 75%-correct angle. However S never heard the real initiation or termination of the pure tones. Directly behind him a few feet away was a second loudspeaker energized as needed by a white noise of about 80 dB SL, i.e., more than enough to mask any possible sound from the test speaker in front. Keying of the speakers was timed so that S first heard the white noise, after which the front speaker (positioned either L or R but quite inaudible) was energized, then after 1/2 sec the noise was turned off for either 1/4 sec or 5 sec, then on again, and after another 1/2 sec the tone (now again inaudible) was terminated, after which the noise also was turned off and the trial terminated with S's judgment L–R of the pure tone.





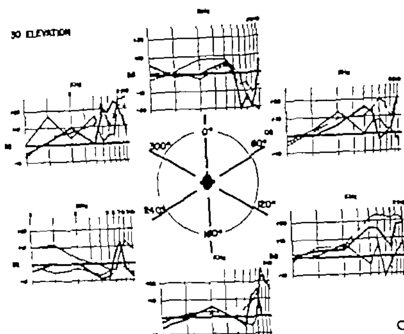


Fig 6 A–C. Effect of the sound shadow on timbre as a function of azimuth. Note. Graphs to the R L of the midline represent the increase in SPL at the R ear over the L, or L over R respectively

By this method of placing the masking loudspeaker in the midline the Dt cues on initiating and terminating the tone were removed from *S* and he was given a temporally non informative window during which he could judge the pure tone L–R Of course

control data were also taken with the 5-sec tone with no masking, i.e. with both DI and Dt information.

RESULTS AND DISCUSSION

Table IX shows no trend for m.a.a. to worsen upon removal of the timing information, even with only a 1/4-sec observation window

A first conclusion might be that timing information is unimportant in localization, but this would be absurd from everyday as well as from laboratory observations. The DI cues as a sound source sweeps around the head as, for example, one stands in a free field and listens to a sound changing azimuth, do not give the impression of sudden shifts of position, as would be the case if the almost erratic DI cues at many frequencies (as seen in Figs. 4 5) were the sole source of directionality Furthermore, experiments too numerous to mention tell us that we are in fact exquisitely sensitive to Dt even in the absence of DI cues.

The case must be that this Exper XII tells us not that DI is prepotent over other cues, but that the auditory mechanism can seize upon any cue available, and make use of it in an efficient manner

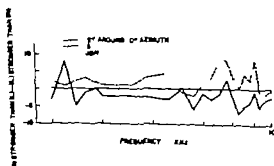

Fig. 7 Effect of the sound shadow at ±5 azimuth on interaural physical DI. S. JDH.

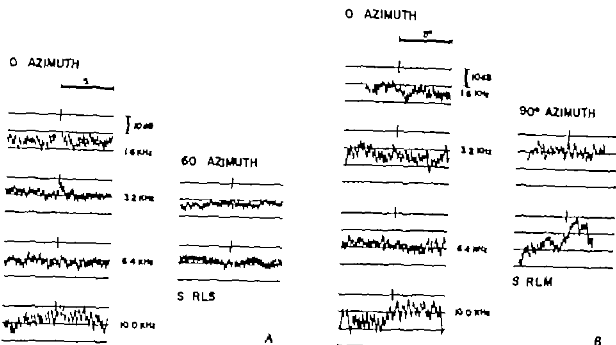

Fig 8 A D Effect of sound shadow on *monaural* minimum audible field across ± 5 azimuth

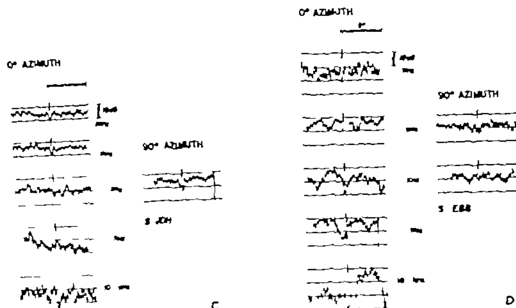
Exper XIII M A A with Interaural Dt as the Only Cue



The converse of Exper XII was arranged, in which an attempt was made to eliminate DI cues while retaining and even exaggerating Dt cues. This experiment was performed by Steinbach (1965) under somewhat different auspices, and under the more direct guidance of Dr Jack Curtis.

APPARATUS AND PROCEDURE

The larger of two sets of pinnae from the Shilling artificial head were mounted on the ends of semi soft plastic tubes, i d = 3/8 inch o d. = 1/2 inch and the other ends sealed into the external auditory meati of 3 adult *Ss* in turn The attenuation of the tubes was 10 dB for a band of noise 220–780 Hz, and 25–29 dB for the bandwidth 740–4 000 Hz. The helmet and tubes allowed for variable tube lenghts to the two ears when the array was supported by a plastic helmet worn by *S* These lengths were either the same or of somewhat different lengths, but always with the same inter pinna distance of 9 5 inches. It could be shown for the case of a sound source off the midline that the interaural Dt per degree azimuth available for L–R judgments was about 10 6 μsec/degree azimuth for the head with no pinnae about 13 3 μsec/degree for the head with inter pinna distance of 9 5 inches and equal-length tubes and about 19 μsec/degree for the same inter pinna distance but with tubes of unequal

Table IX *Contribution to M A A at 3 ? KH (visual ero") possible on interaural intensity cues alone*

length as used here. Thus the condition of unequal-length tubes gives an additional temporal cue of 19–13.3 = 5.7 µsec/degree azimuth re the equal-length condition, and if Dt of this order of magnitude can be used as a cue, m.a.a. should be somewhat superior in the condition of inequality. The fact that DI with this apparatus is negligible was shown by placing the Shilling artificial head, fitted with this apparatus, in the anechoic chamber at the Medical Research Laboratory and recording the sound shadow around the head. A loudspeaker was energized with the bands of noise separately and the output plotted of a Western Electric 640AA microphone at the position of the eardrum. Steinbach's Fig. 14 shows that for the band 740–4 000 Hz, and of course at all lower ranges, there was less than a 1-dB variation across any ±5° azimuth change, over the octant from 0–45°. Thus in this experiment Ss had only Dt to guide them, not DI.

M.a.a. were collected by a method modelled on Mills (1958) on all 3 Ss at 0, 14, 30, and 45° for a low, a middle, and a high frequency noise band without the helmet, and with the helmet bearing equal and unequal tubes.

RESULTS AND DISCUSSION

When results were converted from m.a.a. to Weber fractions so that data from all 4 azimuths could be collapsed, Steinbach's Figs. 11–13 show that all Ss exhibited lawful curves for the two lower bandwidths mentioned. Data from a higher bandwidth of 2.1–5.9 kHz were erratic for all Ss, but are in any case for this purpose uninterpretable since the attenuation difference between the two unequal-length tubes was about 3 dB, and the sound shadows thrown amounted at some azimuths to as much as 0.55 dB/degree (i.e., enough to yield an m.a.a. of 1–2° on a DI cue alone).

These data are interpreted to mean that all Ss used Dt alone to yield quite good m.a.a. In Steinbach's Figs. 11–13 it can be seen that the Dt data from the helmet usually at least equal, and for one S often exceed, control m.a.a. with no helmet, in which of course all possible cues are present.

Whether the increased cue in µsec/degree in the unequal-tube condition, as compared with the equal-tube condition, is made use of by any S is unclear in Steinbach's data.

length as used here. Thus the condition of unequal-length tubes gives an additional temporal cue of 19–13 3 = 5.7 μsec/degree azimuth re the equal-length condition, and if Dt of this order of magnitude can be used as a cue, m.a.a. should be somewhat superior in the condition of inequality The fact that DI with this apparatus is negligible was shown by placing the Shilling artificial head, fitted with this apparatus, in the anechoic chamber at the Medical Research Laboratory and recording the sound shadow around the head. A loudspeaker was energized with the bands of noise separately and the output plotted of a Western Electric 640AA microphone at the position of the eardrum Steinbach s Fig 14 shows that for the band 740–4 000 Hz, and of course at all lower ranges, there was less than a 1-dB variation across any ±5 azimuth change, over the octant from 0–45 Thus in this experiment Ss had only Dt to guide them, not DI

M a a were collected by a method modelled on Mills (1958) on all 3 Ss at 0 14, 30, and 45 for a low a middle, and a high frequency noise band without the helmet, and with the helmet bearing equal and unequal tubes.

RESULTS AND DISCUSSION

When results were converted from m.a.a. to Weber fractions so that data from all 4 azimuths could be collapsed, Steinbach s Figs. 11–13 show that all Ss exhibited lawful curves for the two lower bandwidths mentioned for the two lower bandwidth of ∠.1–5 9 kH Data from a higher bandwidth of ∠.1–5 9 kH were erratic for all Ss, but are in any ca for this purpose uninterpretable since the at tenuation difference between the two un equal-length tubes was about 3 dB and th sound shadows thrown amounted at some az muths to as much as 0.55 dB/degree (Le enough to yield an m.a a. of 1–2 on a D cue alone).

These data are interpreted to mean that Ss used Dt alone to yield quite good m.a. In Steinbach s Figs. 11–13 it can be seen th the Dt data from the helmet usually at le equal, and for one S often exceed, contr m.a.a. with no helmet, in which of course possible cues are present.

Whether the increased cue in μsec/degr in the unequal-tube condition, as compar with the equal-tube condition, is made of by any S is unclear in Steinbach s da

Occasional readings from *Ss* Nos. 2 and 3 trend in that direction.

Although these data were not collected in an echo-free chamber but in an I.A.C. booth 8×10×6 5 ft at General Dynamics/Electric Boat Co Groton Conn. it is not likely that secondary reflections rendered invalid all con clusions.

A more precise comparison between the equal- vs. the unequal-tube condition with much more sharply filtered and restricted bandwidths, and control of DI cues, would be desirable to bear on the questions (1) whether Dt information is as useful at the higher fre quencies, as we would predict and (?) whether the auditory system can yield better m.a.a. than normal when provided with the auditory analogue of a visual range finder

Exper XIV M A A with Noncongruent Physical Cues Symmetrical Dt but Asymmetrical DI

What would be needed to establish prepotency of any cue would be a situation in which two and only two cues were present, but direc tionality of opposite meaning We were able to generate a situation in the free field which *is one analogue of* the *common* DI–Dt *trad* ing *experiments* under headphones, where the Dt cue is as if the sound source were to the L *of midline*, the DI cue to the R. The con tribution of several parameters to the trading relation (in dB/μsec) under headphones is well known. It is unknown in the free field.

APPARATUS AND PROCEDURE

The visual "zero problem was set up as usual and m.a.a collected with a 1/4-sec and a 5-sec "look" at the stimulus, but on random occa*sions half* of the 5-sec trials were performed with a cotton plug in one ear canal. The ef *fect of this plug* at *3.2 kHz* was ascertained by collecting Bekesy tracings in a free field before, *during* and after inserting the cotton. The attenuation provided (6–8 dB see Table X) would be enough for complete lateraliza tion were these interaural DI conditions created under earphones (see Exper VII above)

Table X *Effect on minimum audible angle at 3.2 KH ("visual zero") of noncongruous intensity and timing cues*

Mean	2.2	2.1	.6	7

RESULTS AND DISCUSSION

Although the 6–8 dB DI would be enough by itself to displace the sound image drastically under headphones, it was not enough to counteract very strongly the prepotent Dt cues *Ss* reported that the image when at known 0 azimuth was seemingly displaced a few degree toward the open ear but once *this fact was accounted for* Table X shows that for no S were the m.a.a. worse when a pronounced asymmetry in intensity was introduced. Ordinary experience of course clearly shows that drastic changes in DI do not entirely dislocate sound images, as one can at test who puts his finger repeatedly in his ear *at a cocktail party* and certainly a trading relation exists at the larger DIs but within the region of DI asymmetry of at least 6–8

dB we could establish that Dt takes precedence almost to the exclusion of DI cues.

This experiment of course accords with common experience—those who have upper respiratory infections with reduced audiometry more in one ear than the other for a few days do not feed one cat when its fellow meows, or have any difficulty navigating in traffic. It is possible that very rapid relearning occurs when DI is asymmetrical in ordinary life, but relearning was not apparent in the data from Table X, and it seems therefore an unlikely necessity in daily life.

We conclude as a working hypothesis that Dt cues are used for the most part in localization of sounds in space, and take precedence where other incongruous cues exist, but that if the organism is thrown back upon DI cues, these too can subserve good performance.

Summary

Fourteen experiments were performed on directional hearing in humans in an anechoic chamber of 37 328 cubic feet. Minimum audible angles (m.a.a.) were determined from 125 through 6 400 Hz with four very experienced adults. Sets of m.a.a. were provided by the Method of Constants using either an acoustic or visual cue to signalize zero azimuth, and for the case of a continuously-moving sound source. The acoustic and visual zero experiments yielded m.a.a. of 1–2° at all frequencies, with either a 1/4-sec or 3-sec observation of the stimuli and (once a constant error due to geometry was controlled) at 30 and 60° azimuths. M.a.a. for the moving source yielded somewhat coarser m.a.a. probably due to the fact that both source and head were moving simultaneously. The effect of head movements on the acoustic and visual zero experiments was negligible at 0° azimuth. Successive interaural differential intensity discrimination was equally good at all frequencies and phenomenological azimuths. When the m.a.a. in the free field with cues both of interaural time-of-arrival and of interaural intensity were compared with control studies in the free field eliminating one or other of these cues, and when the two cues were rendered non-congruent, it was found that the m.a.a. by either cue alone was enough to support good m.a.a. at all frequencies; but when the two cues were rendered non-congruent by special techniques in the free field, the cue of time-of-arrival (and of termination) were propotent over the intensity cue up to at least 6–8 dB interaural intensity. Thus a rather large extent of interaural intensity difference exists over which the expected DI/DT trading did not develop, emphasizing the relatively profound effect which time relationships have on directionality.

Zusammenfassung

Vierzehn Experimente wurden in einem echototen Raum von 37 328 Quadratfuss, am Richtungsgehör in Menschen gemacht. Minimumhorbare Winkel (m.h.w. auf englisch m.a.a.) wurden von 125 bis 6 400 Hz mit vier sehr erfahrenen Erwachsenen errechnet. Die Sammlung von m.h.w. wurden durch die Methode der Konstanten gefunden, durch Gebrauch eines akustischen oder visuellen Winkes, um Azimut-Null zu signalisieren, und im Falle einer sich stets bewegenden Schallquelle. Die akustischen und visuellen Null-Experimente ergaben m.h.w. von 1–2 Grad bei allen Frequenzen, entweder mit

Occasional readings from Ss Nos. 2 and 3 trend in that direction.

RESULTS AND DISCUSSION

Although the 6–8 dB DI would be enough by itself to displace the sound image drastically under headphones, it was not enough to counteract very strongly the prepotent Dt cues. Ss reported that the image when at known 0 azimuth was seemingly displaced a few degree toward the open ear but once this fact was accounted for Table X shows that for no S were the m a.a. worse when a pronounced asymmetry in intensity was intro- duced. Ordinary experience of course clearly shows that drastic changes in DI do not en tirely dislocate sound images, as one can at test who puts his finger repeatedly in his ear at a cocktail party and certainly a trading relation exists at the larger DIs but within the region of DI asymmetry of at least 6–8

einer viertelsekundigen oder dreisekundigen Wahrnehmung der Erregungsfaktoren und (nachdem ein gewisser Fehler wegen Geome trie reguliert wurde) bei 30 Grad und 60 Grad Azimut. M h.w für die sich bewegende Quelle ergab etwas rohere m.h.w wahrscheinlich wegen der Tatsache dass sowohl Quelle wie Kopf sich gleichzeitig bewegten. Die Wirkung der Kopfbewegungen auf die akustischen und visuellen Null Experimente war unbedeutend bei Null Grad Azimut Die erfolgende inter aurale differentiale Intensitätsunterscheidung war bei allen Frequenzen ebensogut Als die m h w im freien Feld mit Winken von der interauralen Ankunftszeit und von der inter auralen Intensität mit der den einen oder den anderen Wink ausschliessenden kontrollierten Forschung im freien Feld verglichen wurden, und die beiden Winke nicht kongruent gemacht wurden, wurde entdeckt dass die m.h.w von einem der beiden Winken ge nügten, um gute m h.w bei allen Frequenzen zu unterstützen aber als die zwei Winke durch besondere Ausführungsarten im freien Feld nicht kongruent gemacht wurden, waren die Ankunftszeit und Endwinke vorherrschend über den Intensitätswink bis zu mindestens 6–8 dB interauraler Intensität. Daher existiert eine ziemlich grosse Ausdehnung von inter auralem Intensitätsunterschied, über den der erwartete DI/DT Handel sich nicht ent wickelte, was die ziemlich grosse Wirkung be tont die die Zeitverhältnisse auf Richtungsgehör haben.

Acknowledgment

Several institutions and individuals contributed to this series of experiments. Major support was provided to the C W Shilling Auditory Research Center Groton, Conn. through Contract RD-510 with the US Office of Vocational Rehabilitation and a coetaneous grant generously provided by The Seeing Eye Morristown New Jersey The use of workspace and aluminum loudspeaker tracks at the U.S.N Submarine Medical Research Laboratory Groton Conn. is gratefully acknowledged The Department of Speech at the University of Connecticut kindly supported the drawings of the figures and provided time for writing. Dr Jack Curtis kindly created the tapes used for studying minimum audible angle without head movement and tapes for interaural intensity discrimination. Thanks are also expressed to the subjects who contributed many hours over two years time to the judgments upon which this paper is based.

Introduction

Menière's disease is a term used synonymously with endolymphatic hydrops, labyrinthine dropsy, labyrinthine hydrops, labyrinthine hypertension or even Menière's syndrome. According to Dorland's Medical Dictionary "disease" refers to a group of related symptoms due to a single pathological cause, whereas "syndrome" refers to a group of symptoms occurring together but of diverse causation. The term "Menière's syndrome" is used to denominate all forms of dizziness, vertigo or even ataxia, whether intermittent, constant or slowly remitting, and due to causes of diverse origin such as chronic suppurative otitis media, intracranial vascular accidents or even neurasthenia. A meaning so broad makes the term "Menière's syndrome" inadmissible in a scientific discussion. H. Williams (1965) therefore suggested that this term be discarded and the term "episodic vertigo" substituted in instances of periodic vertigos caused by diverse pathogenics of the labyrinthine system, and that Menière's disease be reserved to those instances of recurring intermittent vertigos meeting the criteria recommended by the Committee on Vertigo by the National Institute for the Study of Neurological Diseases and Blindness (1961).

The etiology of Menière's disease is not completely understood. It is generally accepted that the main pathogenic factor responsible for the clinical symptoms of labyrinthine hydrops is increased hydrostatic pressure within the endolymphatic system (Cawthorn, 1947; Shambaugh, Jr., 1959, 1966, 1968; House, 1964, 1968; Wittmack, 1929; H. Williams, 1965). However, the primary cause which leads to accumulation of endolymph is not uniform and probably varies from one case to another. Therefore, endolymphatic hypertension may have differing symptoms such as deafness, incapacitating vertigo, roaring tinnitus, diplacusis, etc. Manifestations of endolymphatic hypertension are commonly interrupted by a spontaneous remission. Such spontaneous fluctuations complicate the assessment of the efficiency of various therapeutic methods.

At the present time therapy of Menière's disease is restricted to symptomatic alleviation of the incapacitating manifestations by surgical and/or pharmacological decompression of the increased endolymphatic pressure.

The physiology of the inner ear has been the topic of much research with the hope that understanding of normal function of the inner ear would provide clues to understanding the pathological process responsible for Menière's disease. The increased endolymphatic pressure associated with Menière's disease must be viewed according to the anatomical characteristics of the inner ear and the physico-chemical and physiological principles controlling the formation and circulation of the endolymph. Throughout this paper, the more explanatory term "endolymphatic hypertension" will be used interchangeably with Menière's disease and endolymphatic hydrops. A proper plan of treatment will derive from an analysis of the etiology of the endolymphatic hypertension.

Presented at the Meeting of the Texas Ear, Nose, and Throat Society, May 7, 1971, in Houston, Texas.

Clinical manifestations of endolymphatic hypertension

Typical endolymphatic hydrops was shown by H. Williams (1965) to be a "cluster type" of

A primary or secondary disturbance in microcirculation may become a source of accumulation of lymph in any tissue, and this rule can be applied to the circulation of the endolymph. The diagram in Fig. 1 indicates four areas in which a disturbance might cause an *increase in volume of the lymph*, these four potential physiologic errors are therefore analyzed in an abbreviated form.

1 An elevation of the hydrostatic head pressure at the arterial end of the microcirculation (in case of Menière's disease in stria vascularis) *will increase the force which drives* fluid from the capillaries into extra-capillary space (in our case into the endolymphatic space). In such an event the hydrostatic pressure within the endolymph will rise only if the *excess fluid is not eliminated* at an equal rate *back into the blood* either at the venous end in the stria vascularis or by the excretory function of the endolymphatic sac, or by both.

2. Reduction of the osmotic pressure within the blood plasma in the capillaries (e.g. in *hypoproteinemia*) will reduce the return of fluid at the venous end of the capillary bed from the extracapillary space (in our case from the endolymphatic space). An accumulation of water within the endolymph would then occur even though the filtration at the arterial end *remained normal*.

3. *Increased osmotic pressure in the endolymphatic space caused by an excess of hydrophilic hyaluronic acid-protein aggregates will reduce the return-flow at the venous end regardless of the hydrostatic and osmotic pressures existing within the blood capillaries and in spite of retained physiological excretory function of the sac*

4 A blockage of the outlet from the endolymphatic space through the saccal duct (obliteration of the saccal duct) or excretory insufficiency of the saccal epithelium might result in an accumulation of the fluid and its dissolved solutes if such failure is not compensated by the blood capillaries of the microcirculation and the osmoregulators present in the endolymph.

Each of these mechanisms could represent a pathogenic component to hypertension in the endolymphatic space, and each of these factors might result from a different primary pathological process. Thus the etiology of endolymphatic hypertension cannot be explained by a single master mechanism. Because the control of the endolymph circulation results from a coexisting multiple mechanism, an intimate understanding of the formation and movement of the *endolymph* is the only way to clarify the etiology of an individual case of episodic labyrinthine vertigo related to endolymphatic hypertension.

Formation and movement of endolymph

It is commonly believed that the formation *of the fluid part* of the endolymph (water and electrolytes) *takes place by filtration from* the capillary beds of stria vascularis (Cawthorn, 1947 Shambaugh, Jr 1959 Lindsay 1946, Hallpike, 1938 Guild, 1927), from Shambaugh's glands (Shambaugh, Sr., 1908), *from capillaries of the spiral prominence*, and possibly from capillary arcades located in the basal membrane of scala media (Savin, 1965 Hawkins, 1964) these are the vascularized areas within the endolymphatic space (see Fig. 2). Moreover *radioactive isotope studies* of electrolytes in the endolymph and in the perilymph indicate (Rauch et al., 1963 1963 1958, Mnich, 1971) that sodium and potassium may pass through the Reissner's membrane from scala vestibuli into endolymph of the scala media against the high gradient of osmotic pressure. These observations therefore indicate that the electrolyte shift across the Reissner's membrane must be an *active* metabolic process selectively determined by the membrane. *One must not forget however a basic biologic fact that the shift of water and electrolytes from one compartment to another is controlled by two agencies. (1) osmotic equilibration between two neighboring compartments; and (2) an active metabolic property of proteins within the cell's*

disorder which when fully developed may completely incapacitate the patient fortunately such extremes of the disease occur infrequently and are interrupted by long remissions. Many patients in the milder stages of the disorder learn to live a more or less normal life by avoiding activities of precision while the symptoms last.

The reader may find a thorough discussion on the clinical picture of Menière's disease in articles written by Shambaugh Jr (1966 1968) and H. Williams (1965) The four cardinal manifestations of endolymphatic hydrops need not each one to be present in all cases. (1) The impairment of hearing which tends to fluctuate in the early stages, is probably an expression of changing osmotic or hydrodynamic pressure of endolymph within the cochlear canals the hearing is chiefly affected in the low tone range extending to the high tone range in the later stages of the disease. (2) Tinnitus may vary from mild buzzing to a roaring overpowering noise (3) Vertigo ranges from a mild unsteadiness lasting a few seconds to abrupt loss of balance, sometimes with falls followed by true vertigo which may completely incapacitate the patient for several hours or a day (4) Fullness in the homolateral ear or in the head is regarded by Lindsay (1946) as an important diagnostic symptom in endolymphatic hydrops. Other symptoms such as impairment of discrimination of speech recruitment of loudness, diplacusis, nystagmus nausea and vomiting are often associated with the active stage of the disease. All these signs, alone or in various combinations, are expressed in a fluctuating but steadily progressive course Long periods of mild manifestations may be interrupted by a vertiginous attack with or without other symptoms. In a complete remission which may occur "spontaneously or be induced by therapy all manifestations may subside completely or be grossly reduced in intensity Since spontaneous remissions are characteristic of this disorder there is always an element of doubt as to whether a remission was induced by therapy or not The reason for remission or relapse can be surmised but it can not be proven by our present methods because the etiology of endolymphatic hypertension is not completely understood

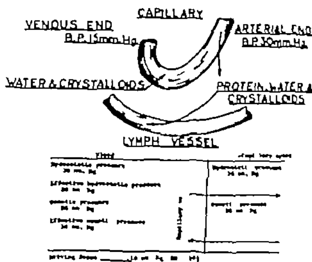

Fig 1 Diagrammatic presentation of dynamics of capillary circulation of tissue fluids in physiological conditions. (Reproduction by kind permission of the authors (Best & Taylor 1961) and publisher (Williams & Wilkins, 1961)).

Physiopathology of endolymph and endolymphatic system

The detailed mechanism of the physiopathology operating in the endolymphatic hypertension is far from being understood. The available data from animal experiments and from human pathology as well as from clinical symptoms [critically reviewed by Shambaugh, Jr (1966) and by H Williams (1965)] tend to indicate that no one single mechanism can be pointed out as the master mechanism" by which all cases of Menière's disease can be explained. Nevertheless, two topics are of fundamental importance

1 the basic principles controlling microcirculation of physiological fluids in all living tissues

2. the specific local anatomical and physiological factors controlling the microcirculation of the endolymph.

the endolymph is the epithelium which lines the endolymphatic sac. But McNally (1926) and later Lindsay et al. (1952) found in their experiments that the surgical removal of the sac and its duct had no significant influence on the pressure in the remaining intact endolymphatic space. However more recent studies by Kimura & Schuknecht (1965) by modified techniques demonstrated a delayed endolymphatic hypertension in some of the operated animals.

The hypothesis has been presented that the water of the endolymph with its dissolved or suspended molecules is excreted by the epithelium of the sac into the interstitial compartment of the loose connective tissue in the perisacal space, which normally contains a well-developed capillary network. A striking absence of the capillaries around the distended sac found in certain cases of Menière's disease was thought by Shambaugh, Jr (1968) to suggest a primary pathogenic cause of retention of endolymph which led to endolymphatic hydrops. Nevertheless, the same effect is more likely to be caused by a reverse mechanism: the primarily distended sac caused by the accumulation of the endolymph could occlude the capillaries by pressing and stretching them thus leading to an ischemia which, if persistent, might eventually lead to an ischemic atrophy of the perisacal connective tissue. Naturally such elimination of the capillary circulation from the perisacal connective tissue would aggravate a primarily existing endolymphatic hydrops.

The endolymph excreted and mixed with the perilymph in the perisacal space is next drained into the lateral cranial sinus (Guild, 1927), or mixed directly with the cerebrospinal fluid. The excretory action of the sacal epithelium must be regarded therefore as a specific function of its columnar epithelial cells (Guild, 1927). This biological function must be warranted by the general principles of physiologic energy exchange in which thyroid hormone, cyclic AMP, prostaglandins, etc. play an important role. The resorption of endolymph in the stria vascularis should be regarded, on the other hand, as the effect run exclusively by physicochemical forces.

The formation of endolymph in the endolymphatic space [corti-endolymph (Engstrom 1960), cochlear endolymph, sacal endolymph] should be viewed in identical terms as that of the formation of interstitial fluids in peripheral subcutaneous tissue, or of fluids in other serous cavities, such as joint cavities (Asboe Hansen, 1950). The composition of these fluids is somewhat similar to, but by no means identical with, the endolymph: the chief difference lies in the quality and the quantity of the proteins present in these fluids. Nevertheless, the hydrostatic and osmotic dynamics which control the circulation of such fluids are identical to those which control that of endolymph.

The protein moiety in the endolymph is formed by the epithelium lining of the endolymphatic space in a fashion similar to that of the lymph in the lymphatic spaces in the peripheral tissues, or to that of the serous fluids in other serous cavities, which is produced by fibroblasts in the former and by the epithelium in the latter instances. Diagrammatic presentation of the hydrostatic and osmotic forces which control the circulation of these peripheral fluids is shown in Fig. 1 (Best & Taylor 1961). The blood capillary loop shown in this diagram might represent a peripheral capillary bed of stria vascularis. The interstitial fluid formed in the peripheral tissues, for instance in the subcutaneous tissues, might correspond to the endolymph present in the scala media. The flow of the lymph in the peripheral lymphatic capillaries may be compared to the successive shift of the endolymph going in two directions, to the endolymphatic sac and to the stria vascularis. If the interstitial spaces of the peripheral tissues were locked up in such an area as the endolymphatic space, and the entire diagram considered to be a capillary bed located within the temporal bone—the formation, circulation and equilibration between the compart

structure which separate the two compartments.

Proteins and their derivatives are the living elements in the body which can either specifically interact or repel electrolytes, thereby either retaining them within the cytoplasmic medium (or fluid of one compartment) or rendering them available to osmotic shift. The shift of electrolytes from perilymph across the Reissner's membrane is the basis for the theory of "radial flow" of endolymph (Naftalin & Harrison 1958) in contradistinction to "longitudinal flow"—from stria vascularis to the sac. It has also been shown in animals (Rauch 1963 Mnich, 1971) that the radioactive cations which were shifted into endolymph from perilymph were rapidly eliminated into the general circulation via the venous end of the microcirculation of stria vascularis. In other words, the permanent residence of electrolytes within the endolymph is a secondary phenomenon which depends on the type of proteins present in the endolymph. The movement of the electrolytes from one compartment to another is physically carried out by the equilibration of the osmotic gradients in the adjacent compartments, and they are shifted *by a passive driving force*. But the availability of free electrolytes depends on their release from the conjugation with the protein molecules. Therefore there are two types of the endolymphatic hypertension (1) that which is *produced by the hyperosmolality of the endolymph resulting from the altered proteins* and this type anatomically does *not* produce a hydrops of the endolymphatic sac (2) that which is *produced by the hyperosmolality caused by abnormal proteins and bound to them electrolytes and this type of endolymphatic hypertension presents an endolymphatic hypertension with the distended endolymphatic space (hydrops).*

Perhaps at this point of the discussion it may be appropriate to emphasize the unique physio-chemical conditions existing within various compartments of the endolymphatic space. Although actual anatomical barrier is non-existing yet there are at least three (or more) different compartments, in two of which (sacal and cochlear) the composition of the endolymph differs significantly (Silverstein 1966 1971). The composition of the endolymph of the third compartment (cortilymph) is not as yet known in detail. The fact that the endolymph moves freely through both compartments, each retaining its specific characteristics, indicates that the element which controls the qualitative differences of endolymph in each compartment must exist within the endolymph itself such a specific action could only come from a protein moiety which differs in each compartment

The binding and freeing of water and electrolytes which permits the endolymph to be shifted (not flow!) must serve a useful purpose in the mechanism of hearing. The supply of essential nutrients by the endolymph for the organs of hearing and equilibrium is not only most logical but is also well-documented. However the discrepancy in the compositions of various endolymphs must also possess other than nutritional effects. Since the lymph from the various cochlear compartments differs significantly pathologic changes in the form of quantitative or qualitative alternations in proteins might therefore affect one cochlear compartment leaving the other two unaffected, or two of the three compartments could be simultaneously involved Therefore an increased hydrodynamic pressure located for instance in the cochlear duct might not necessarily cause a distension of the endolymphatic sac And a localized hyperosmolality of the cortilymph which might conceivably impede the mechanism of hearing, might not necessarily be reflected in a *hyperosmolality of the* cochlear or sacal endolymph If this is true a therapeutic drainage of the sac by fistulation or by enlargement of the space of the sacal environment might not affect the symptoms of every case of endolymphatic hypertension.

It has been believed (Guild, 1927 Lawrence et al. 1961) that the main resorptive area for

toneum (Kocen, 1952, Levine, 1960; Lange, 1944). Under same pathological conditions hyaluronate mucopolysaccharides may also accumulate in the vitreous of the eye (Larson, 1958; Dische & Zelmanes, 1955). The symptoms produced by expansion of fluids in the pleura, pericardium or peritoneum are less dramatic than in the endolymphatic space, because the expansibility of the endolymphatic space is, for practical reasons, nonexistent.

Circulation to and from the endolymph is another factor influencing the pressure in this organ. The water and water solutes flow in two directions, from the arterial end of the capillary beds of the stria vascularis to the venous end of the capillary beds of stria vascularis and to the endolymphatic sac; each route may take over the function of the other when an obstacle blocks its passage. The driving force of the in-and-out flow of water in the physiological state equals 10 mmHg (see Fig. 1). When the osmotic pressure of the endolymph rises, as the result of water binding by the hyaluronate mucopolysaccharides, the filtration of the water at the arterial end in the stria vascularis proceeds until the *osmotic and hydrostatic driving force* (20 mmHg) becomes equal on both sides of the capillary wall. On the other hand, increased osmotic pressure in the endolymph prevents the outflow from the endolymph normally generated by *osmotic driving force of the blood plasma proteins* at the venous end of the capillary loops in stria vascularis. In these circumstances maintenance of a near normal endolymphatic flow may rest on the excretory function of the sac epithelium, provided the action of hyaluronidase on the hyaluronate mucopolysaccharides will liberate free water. Thus, three factors ultimately control the physiologic flow of the endolymph.

(1) filtration rate of water and crystalloids at the arterial end (controlled by hydrostatic pressure) and their reabsorption rate at the venous end (controlled by the osmotic pressure exerted by plasma proteins)

(2) osmotic pressure of the endolymph itself

Table I. *Abnormal findings in metabolic survey of 250 patients with Menière's disease*

(controlled by the amount of the molecules of hydrophilic hyaluronate mucopolysaccharides controlled by hyaluronidase

(3) the excretory clearance by the epithelium of the sac (the control of this function is not conclusively known).

The other factor which has been suggested as influencing the endolymphatic pressure and endolymph flow such as fluctuations in the hydrostatic pressure of the cerebrospinal fluid caused by changes of the position of the whole body from upright to recumbent and vice versa, should be regarded as transitory. Such an effect could exert a cushioning or "milking" effect of cerebrospinal fluid upon the sac to prevent transmission of changes in intracranial pressure to the inner ear which might disturb equilibrium (Allen, 1964). These effects cannot, however, have a continuous effect on endolymphatic pressure.

Rhythmic expansion and collapse of the endolymphatic pressure might also be caused

Fig 2 Diagrammatic presentation of factors controlling the circulation of endolymph. Hyaluronidase is secreted into endolymph by mast cells located in the membranes of the endolymphatic space (Poulsen, 1966) Reissner's membrane is permeable to water crystalloids and other small molecular substances (Naftalin et al. 1958 Mnich 1971) Anti-hyaluronidases penetrate into endolymph via capillarized organs in endolymphatic spaces. Free" water is presented as round circles, "bound water to hyaluronate mucopolysaccharides are presented as circles surrounded by interrupted lines.

Histamine and its analogue (Schayer 1964) acts on the pre-capillary sphincter thereby regulating hydrostatic pressure in the capillary bed and the rate of filtration through the capillary wall.

ments of the endolymph would still be controlled by the identical osmo-dynamic principles as when it represented the interstitial fluids or serous fluids in various serous cavities. However the composition of proteins in the endolymph (Silverstein 1971) indicates that it is not a simple transudate from the plasma and the difference from other serous fluids being probably because of the adaptation to the highly sensitive mechanics of hearing and equilibrium. *The protein moiety of the endolymph therefore acquires a specific significance in characterization of the endolymph and the whole problem of endolymphatic hypertension pivots on the nature of the protein.*

Role of protein in circulation of endolymph

Proteins may be secreted physiologically by the endolymphatic epithelium or may be exuded through the capillaries in an allergic, toxic reaction bacterial viral and fungal infection. There are three varieties of such proteins

(1) mucopolysaccharides of the hyaluronic acid order (large hydrophilic molecules)

(2) hyaluronidase an enzyme which depolymerizes hyaluronate mucopolysaccharides by splitting off the molecule of hyaluronic acid, thereby depriving them of hydrophilic properties

(3) anti hyaluronidases which control the action of hyaluronidase (not all anti hyaluronidases belong to proteins)

The accumulation of hyaluronate mucopolysaccharides in any serous cavity or tissue causes an accumulation of fluids. In myxedema such an accumulation might be found in the pericardium (Askensay 1898 Hurxthal 1935) in pleura (Farayoni, 1952) or in peri-

um (Kocen, 1952, Levine, 1960; Lange,). Under some pathological conditions ronate mucopolysaccharides may also mulate in the vitreous of the eye (Larson , Dische & Zelmanes, 1955). The symp- produced by expansion of fluids in the ra, pericardium or peritoneum are less atic than in the endolymphatic space be e the expansibility of the endolymphatic e is, for practical reasons, nonexistent.

rculation to and from the endolymph is her factor influencing the pressure in this n. The water and water solutes flow in directions, from the arterial end of the llary beds of the stria vascularis to the us end of the capillary beds of stria vas- ris and to the endolymphatic sac; each e may take over the function of the other n an obstacle blocks its passage. The driv- force of the in-and-out flow of water in physiological state equals 10 mmHg (se- 1). When the osmotic pressure of the olymph rises, as the result of water bind- by the hyaluronate mucopolysaccharides, filtration of the water at the arterial end e stria vascularis proceeds until the *osmot and hydrostatic driving force* (20 mmHg) omes equal on both sides of the capillary . On the other hand, increased osmotic sure in the endolymph prevents the out from the endolymph normally generated *osmotic driving force of the blood plasma teins* at the venous end of the capillary s in stria vascularis. In these circum- ces maintenance of a near normal endo- phatic flow may rest on the excretory ction of the sac epithelium, provided the on of hyaluronidase on the hyaluronate copolysaccharides will liberate "free er". Thus, three factors ultimately control physiologic flow of the endolymph.

1) filtration rate of water and crystalloids the arterial end (controlled by hydrostatic ssure) and their reabsorption rate at the ous end (controlled by the osmotic pres- e exerted by plasma proteins);

2) osmotic pressure of the endolymph itself

by fluctuations in the systolic and diastolic expansions of the arterioles and met-arterioles of the capillary beds in the vascularized organs of the endolymphatic space This effect could only represent an insignificant role which under physiological conditions could not produce a steady effect upon either the flow or the pressure of endolymph. This mechanism however might produce pressure "waves in the endolymph in pathological conditions such as arterial hypertension or in diseases connected with an increased pulse pressure such as aortic regurgitation or *thyrotoxicosis*. Transitory dizziness is oftentimes associated with these conditions, but such vertiginous symptoms cannot be classified as Menière's disease although transitory hypertension in the endolymphatic space is the cause of them. On the other hand, it is well known that Menière's disease is seldom associated with high blood pressure aortic regurgitation or thyrotoxicosis.

In an analysis of the *metabolic findings* recorded in our series of 250 patients diagnosed as Menière's disease (Tables I and II) a dysproteinemia of plasma proteins has been found a common feature The consistency in alterations in the quality of plasma proteins suggested that the primary pathogenic mechanism operating in patients with Menière's disease exists in the whole organism and inner ear pathology is only an extension of the pathology in which the whole organism is involved To substantiate such a contention we have studied the problem by two methods (1) *histochemical* of the cochlea from a normal and from an ear of a patient with Menière's disease and (2) *biochemical analysis of the inner ear fluids* and the blood plasma from the patient with Menière's disease as well as the plasma from a normal individual.

Histological section of a normal human ear (Fig. 3) and of an ear from advanced Menière's disease were simultaneously stained with toluidine blue which specifically stains free hyaluronic acid ("H") giving dark purple-blue color however if "H is conjugated with mucopolysaccharides this tinctorial property is completely lost. The large molecules of hyaluronate mucopolysaccharides possess a strong water-binding property (*hydrophylic*) whereas mucopolysaccharides without "H" depolymerized by enzyme *hyaluronidase* ("HD") lose this tinctorial property and become hydrophobic In Fig. 4 staining with toluidine blue gave yellow-brown color proving thereby complete absence of H as a result of the deficit of depolymerizing action of hyaluronidase Naturally the endolymph could not be demonstrated in this section because it was destroyed in process of preparation

The *biochemical studies* by electrophoretic technic (Fig. 5) the endolymph perilymph cerebrospinal fluid and plasma proteins from a patient with advanced Menière's disease and plasma proteins from a normal individual were analyzed. The details of the technic are described in the legend of Fig 5 In series C (endolymph) strip No 1 shows normal amounts of hyaluronic acid as compared with control series A strip No 1 but if acted upon with double amount of hyaluronidase in strip 4 in series C released hyaluronic acid from hyaluronate mucopolysaccharides grossly exceeded the quantities of H released in strip No. 4 of control series A. The H" of serum

of the same patient with Menière's disease in series C in the strips 7 and 8 showed also a great accumulation of H⁺ equal to that found in the endolymph of the same patient. The cerebrospinal fluid from another patient with Menière's disease who was previously treated with shunt between the sac and subarachnoid space (series D) had similar accumulation of hyaluronate mucopolysaccharides which yielded similar amounts of H⁺ to those found in endolymph from patient with Menière's disease (series C).

We have concluded therefore that:

1. *Endolymphatic hypertension is an extension of a pathology involving the whole organism but clinical manifestations are dramatized in the inner ear*
2. *The primary cause of endolymphatic hypertension is a deficit of the hyaluronidase action caused by various etiological factors. This leads to accumulation of hyaluronate mucopolysaccharides in the endolymphatic space causing either a hydrops with all consequences of mechanical and nutritional sequelae or damaging the organs located in the endolymphatic space by dehydration exerted by hyaluronate mucopolysaccharides without forming a hydrops.*

The cause of the deficit of hyaluronidase action may originate in various mechanisms: (1) it could be either *hereditarily transmitted* and be triggered by any metabolic stress, or (2) an infection with a specific virus with the affinity to endolymphatic organs, or any infection, e.g. bacterial or fungal, or (3) toxic stresses such as hypersensitivity or chemical toxicity could eliminate hyaluronidase action (see Fig. 2). The other two factors, i.e., changes in the hydrostatic and/or osmotic pressure in the blood in the vascularized areas, or isolated dysfunction of the endolymphatic sac, could have only a contributory effect in most instances. Although neither increased hydrostatic pressure within the arteriolar capillaries nor hypoproteinemia in the blood can be regarded as a primary mechanism in endolymphatic hydrops, the artificial reduction of the head pressure in the capillaries and/or elevation of the osmotic pressure in the circulating plasma can be utilized *in pharmacological decompression* of the endolymphatic hypertension for symptomatic alleviation of symptoms of Menière's disease (see below).

Lindsay et al. (1947 1952) have ruled out the excretory failure of the saccal epithelium as a primary etiological mechanism of the labyrinthine hydrops by removal of sac with its duct in animals without causing significant changes in the endolymphatic pressure. Although in more sophisticated technic Schuknecht & Seifi (1963) and Kimura & Schuknecht (1965) by the removal of the sac have caused an experimental endolymphatic hypertension but only in a few animals of the whole series. Since the majority of the operated animals did not develop any signs of endolymphatic hypertension, those few positive ani-

as 1 1 1 2, 1 3. The intensity of blue staining as approximately equal in all strips as in series A 1.
I series B (serum from normal person) the blue color slightly intensified with increased amount of "HD" added to serum shown in strips B 2, 3 and 4 as result of depolymerizing of free "H" from normal amounts of hyaluronate mucopolysaccharides present in normal blood by greater quantity of "HD".
I series C 1 (endolymph from Menière disease patient) the amount of depolymerised free "H" greatly increased with increased amount of "HD" added to endolymph proving that accumulated hyaluronate mucopolysaccharides required more "HD" action for the liberation of free "H".
I series C 5 6,7 and 8 (serum from the same patient) accumulation of hyaluronate mucopolysaccharides was equally high as those found in the endolymph (C 1,2,3 and 4).
I series D (CSF from patient with Menière's disease decompressed by shunt between sac and subarachnoid space) the conditions are similar to those in endolymph and serum from patient with Menière disease.
I series C 9 10 11 and 12 (perilymph from patient with Menière's disease) the amount of free "H" was found in much lesser quantities than those found in endolymph.

thereby creating a deficit in depolymerizing action of normal mucopolysaccharides (*deficit of hyaluronidase*).

3. Production of structurally normal mucopolysaccharides in normal quantities which cannot be depolymerized by normal quantities of hyaluronidase on account of the high titer of anti-hyaluronidases, (*excess of anti-hyaluronidases*).

All three variants might exist either alone or in various combinations with the same consequences, that is, excessive binding of water thereby restricting the movement of the endolymph. Presence of the hydrated mucopolysaccharides which have not released the water is important because (1) the flow of nutrients to the organs located in the endolymphatic space is restricted, and (2) the hyperosmolality of the endolymph increases the pressure upon the organs located within the endolymphatic space. According to the prevalence of the individual pathogenic factors, the manifestations of the endolymphatic hypertension will vary from one case to another

Hyaluronidase/Anti-hyaluronidase ratio

The physiological depolymerizations of the hydrophilic mucopolysaccharides by hyaluronidase is controlled by numerous factors, biochemical, immunological, and endocrinological These factors are collectively designated as *anti-hyaluronidase effect* or *atio* The collective term of *anti-hyaluronidases* represents, therefore three groups of factors which may inactivate hyaluronidase (Giblan, 1951)

1 *Plasma anti-hyaluronidase* is physiologically present in the blood in varying concentrations (referred to as the titre of anti-hyaluronidase) Chemically it is a glycoprotein (Meyer et al. 1936) which inactivates the depolymerizing action of hyaluronidase by splitting of hyaluronic acid from hyaluronate mucopolysaccharides. The origin of plasma anti-hyaluronidase is not known. The physiological function of plasma anti-hyaluronidase is to maintain normal hydration of tissues and physiological fluids by inactivating the depolymerizing action of hyaluronidase or in turn, by withholding its inhibitory action, thus sustaining the tissue turgor and physiological volume of various serous fluids. A high titre of plasma anti-hyaluronidase may cause elastic edema (metabolic edema) or hydrops in serous cavities. Conversely a low titre of plasma anti-hyaluronidase leads to dehydration (metabolic dehydration). This form of anti-hyaluronidase travels electrophoretically with globulins, and acts by an immunological mechanism.

2. *A hormonal anti-hyaluronidase effect* may derive from a deficit of thyroid hormone (th.h.) which is required for the formation of proteins in general, and hyaluronidase in particular Thyroidectomized guinea pigs with fully-developed myxedema do not possess hyaluronidase at all these guinea pigs accumulate mucopolysaccharides in all organs. When a th.h. is adequately supplied hyaluronidase reappears and is followed by a normal rate of depolymerization of hydrophylic mucopolysaccharides (Asboe Hansen, 1954). Studies of the myxedematous guinea pigs by Poulsen (1966) and thyroidectomized sharks by Vilstrup (1954) have shown a high content of hyaluronate mucopolysaccharides in the endolymph, which are known to possess the water-binding capacity

3 *An immuno-chemical anti-hyaluronidase action* can result from compounds originating outside or inside the organism, such as bacterial toxins ("Spreading factor" (Duran-Reynolds, 1929)) protein catabolites in anaphylactic reactions, heavy metals, and the like.

Thus we regard a deficit in the depolymerizing action of hyaluronidase as the most common primary etiological mechanism of endolymphatic hypertension. Secondary factors such as increased capillary permeability in the stria vascularis or dysfunction of the excretory action of the sac and its duct (which might end in the obliteration of the saccal duct and vestibular aqueduct) increase the severity of the hydrops and may create an intractable form of the disorder

mals must be accepted as an experimental coincidence.

Normally in cats, the endolymph of the endolymphatic sac is more concentrated and possesses a viscous character as compared with endolymph from the cochlear duct, chiefly because of concentration of proteins is about forty times higher: potassium in turn is greatly reduced and sodium is increased (Silverstein, 1966). This suggests that the water and potassium are eliminated by the epithelium of the sac but this does not imply that an alternate route for the excretion of water and potassium from the endolymph by venous return in the stria vascularis does not exist. If sacal excretion is blocked as a result for instance of the obliteration of the capillary net caused by a distended sac, and simultaneously elimination of water by venous return is reduced on account of hypoproteinemia of the blood plasma, lost or reduced function of the sac might definitely aggravate an existing hypertension in the endolymphatic space. In other words, the insufficiency of the sac's excretory function may aggravate but not primarily cause endolymphatic hypertension or if it does, it occurs on rare occasions in conjunction with dysproteinemia existing in the whole organism.

The obliteration of the vestibular aqueduct found by Clemis & Salvassori (1968) is regarded by the authors as a contributory cause of the endolymphatic hydrops. Using radiological studies they found absence of the vestibular aqueduct in prevailing majority of true Menière's disease. On histological examination of temporal bone they found that the vestibular aqueduct was either completely obliterated or its location marked only by a filiform band of connective tissue. They have suggested that the absence of the vestibular aqueduct (and the sacal duct located in the aqueduct) might be explained by either an error in the embryological development or by disease after birth. Other workers found no pre-existing developmental anomaly (Anson 1968) and no abnormality of petrous bone from patients with Menière's disease was found (Schucknecht 1968). It is therefore more probable that the absence of vestibular aqueduct (and sacal duct) is a secondary phenomenon caused by primary pathogenic noxa which on the other hand, caused endolymphatic hypertension and, later inflicted its destruction followed by a complete calcification of the destroyed sacal duct or the debris of the wall of the sacal duct became organized into the band of filiform connective tissue.

Physiopathology of mucopolysaccharides in endolymph

Metabolic studies on patients with Menière's disease shows that reduced oxygen uptake and dysproteinemia in the blood plasma (Table I) are the commonest metabolic error. These two basic physiological factors control normal metabolic processes of all organs. The same pathogenic mechanism which caused abnormality in these two physiological factors also act on the formation and function of the endolymphatic space. The endolymph obtained from the few patients with Menière's disease available for such analysis showed the same dysproteinemia in the endolymph as in the plasma proteins. This was revealed in the electrophoretic pattern as an excess of hyaluronate mucopolysaccharides (Fig. 5). Therefore a discussion of the condition under which mucopolysaccharides might be expected to accumulate in the endolymph is needed to clarify the pathogenic mechanism operating in endolymphatic hypertension.

Three factors can lead to the accumulation of hydrophylic mucopolysaccharides in body cavities (including endolymphatic space) and change their function *without necessarily increasing their volume*.

1. Excessive production of hydrated form of mucopolysaccharides resistant to the depolymerizing action of normal hyaluronidase (*excess of stable hydrated mucopolysaccharides*).

2. Reduced production of hyaluronidase

thereby creating a deficit in depolymerizing action of normal mucopolysaccharides (*deficit of hyaluronidase*).

3 Production of structurally normal mucopolysaccharides in normal quantities which cannot be depolymerized by normal quantities of hyaluronidase on account of the high titer of anti-hyaluronidases, (*excess of anti-hyaluronidases*).

All three variants might exist either alone or in various combinations with the same consequences, that is, excessive binding of water thereby restricting the movement of the endolymph. Presence of the hydrated mucopolysaccharides which have not released the water is important because (1) the flow of nutrients *to the organs* located in the endolymphatic space is restricted, and (2) the hyperosmolality of the endolymph increases the pressure upon the organs located within the endolymphatic space. According to the prevalence of the individual pathogenic factors, the manifestations of the endolymphatic hypertention will vary from one case to another

Hyaluronidase/Anti-hyaluronidase ratio

The physiological depolymerizations of the hydrophilic mucopolysaccharides by hyaluronidase is controlled by numerous factors, biochemical, immunological, and endocrinological. These factors are collectively designated as *anti-hyaluronidase effect* or *ratio*. The collective term of *anti-hyaluronidases* represents, therefore, three groups of factors which may inactivate hyaluronidase (Gibian, 1951).

1 *Plasma anti-hyaluronidase* is physiologically present in the blood in varying concentrations (referred to as the titre of anti-hyaluronidase). Chemically it is a glycoprotein (Meyer et al. 1936) which inactivates the depolymerizing action of hyaluronidase by splitting of hyaluronic acid from hyaluronate mucopolysaccharides. The origin of plasma anti-hyaluronidase is not known. The physiological function of plasma anti-hyaluronidase is to maintain normal hydration of tissues and physiological fluids by inactivating the depolymerizing action of hyaluronidase or in turn, by withholding its inhibitory action, thus sustaining the tissue turgor and physiological volume of various serous fluids. A high titre of plasma anti-hyaluronidase may cause elastic edema (metabolic edema) or hydrops in serous cavities. Conversely a low titre of plasma anti-hyaluronidase leads to dehydration (metabolic dehydration). This form of anti-hyaluronidase *travels* electrophoretically with globulins, and acts by an immunological mechanism.

2. *A hormonal anti-hyaluronidase effect* may derive from a deficit of thyroid hormone (th.h.) which is required for the formation of proteins in general, and hyaluronidase in particular. Thyroidectomized guinea pigs with fully-developed myxedema do not possess hyaluronidase at all, these guinea pigs accumulate mucopolysaccharides in all organs. When a th.h. is adequately supplied hyaluronidase reappears and is followed by a normal rate of depolymerization of hydrophylic mucopolysaccharides (Asboe Hansen 1954). Studies of the myxedematous guinea pigs by Poulsen (1966) and thyroidectomized sharks by Vilstrup (1954) have shown a high content of hyaluronate mucopolysaccharides in the endolymph, which are known to possess the *water-binding capacity*

3 *An immuno-chemical anti-hyaluronidase action* can result from compounds originating outside or inside the organism such as bacterial toxins ("Spreading factor" (Duran-Reynolds, 1929)) protein catabolites in anaphylactic reactions, *heavy metals, and the like.*

Thus we regard a deficit in the depolymerizing action of hyaluronidase as the most common primary etiological mechanism of endolymphatic hypertension. Secondary factors such as increased capillary permeability in the stria vascularis or dysfunction of the excretory action of the sac and its duct (which might end in the obliteration of the saccal duct and vestibular aqueduct) increase the severity of the hydrops and may create an intractable form of the disorder

An endocrinological survey of 250 patients with Menière s disease (Table II) has revealed deficiency in th.h. in one form or an other in 89 2% of all cases studied. It is therefore suggested that the th h. deficiency led to a general deficiency of protein formation and to an inadequate function of hyaluronidase. A state of molecular disease of proteins coexists in other organs but the degree of dysproteinemia is either not sufficiently advanced or the methods used are not sensitive enough to demonstrate anatomic changes and/or dysfunction of other organs.

The hypometabolic states which contribute to a low titre of hyaluronidase in the endolymph are associated with other factors which might secondarily influence the depolymerizing action of hyaluronidase. For example, a *deficit of th.h. facilitates invasion of the or* ganism by various living pathogens. Hyaluronidases of bacterial or fungal origin (also called "spreading factor" (Duran-Reynolds, 1929)) may act as an antigen and induce the formation of specific antibodies directed against the bacterial hyaluronidases. A subsequent Ag/Ab reaction would immobilize the bacterial hyaluronidase. By cross-specificity these same bacterial anti hyaluronidases may act upon the organism s own hyaluronidase and block *its depolymerizing action*. Pathogens which exist in the body in an apparent state of physiological coexistence with the host also may produce toxins which act as enzymic inhibitors. These enzymic inhibitors may invade the organism in *sub-toxic doses* without causing a local reaction at the portal of their entry Constant flooding of the organism by enzymic inhibitors from subclinically involved organs is often not appreciated either by the patient or by his physician be cause the cause and *effect relationship* is not apparent for instance between Menière s disease and chronic prostatitis or chronic cervicitis.

In our series of 250 patients with Menière s disease the incidence of attenuated chronic infections was 91 2 % (Table III). About half of these were prostatic or vaginal infections. Control of the infections by specific anti-bacterial or anti fungal agents along with hormonal replacement resulted in remission of the Menière s disease which promptly relapsed when local or systemic acute infectious agents were discontinued Hormonal replacement in these patients was insufficient for control of the disease

Bacterial and fungal toxins are not the sole inhibitors which may affect the depolymerization of mucopolysaccharides by hyaluronidase. A group of organic and inorganic compounds either penetrating the organisms from without or originating inside the body may also interact with and inhibit the depolymerizing action of hyaluronidase These

reactions are usually of competitive character and as such, they are reversible. To these enzymic inhibitors belong compounds such as heparin when used in higher than physiological concentrations, hyaluronic acid in the acetylated, sulfated, and nitrated salts—sulfated esters of cellulose xylan, aliphatic alcohols, anionic dyes, bile salts, sulfated steroids, derivatives of diphenols, aurin, tricarboxylic acid, di- and trivalent metals, especially Fe Fe^{++} Cu Zn and half-products of protein metabolism, such as toxic catabolites originating in anaphylactic reactions (Meyer et al. 1936).

Anatomical changes in inner ear in Menière's disease

The histologic appearance of a normal labyrinth from an ear involved in "labyrinthine hydrops" is presented in Figs. 3 and 4. The staining of both sections with toluidine blue indicates a low content of hyaluronate mucopolysaccharides in the petrous bone, and in the membranes of the endolymphatic system in the normal ear (Fig. 3). In Fig. 4 the advanced stage of Menière's disease shows the destructive effects of endolymphatic hypertension with accumulation of hyaluronate mucopolysaccharides in the tissues of the inner ear the endolymph is not visualized in both sections. Both sections were stained by the same technic simultaneously The much stronger purple color of all tissues in Fig. 3 (free hyaluronic acid) results from the adequate depolymerization of mucopolysaccharides by hyaluronidase predominance of pale-yellow background in Fig. 4 is caused by the accumulation of hyaluronate mucopolysaccharides resulting from a low titre of hyaluronidase action causing a deficit in depolymerization.

The gross and microscopic pathological changes found in endolymphatic hydrops (Lindsay et al., 1952 Mygind, 1946 Silverstein, 1966) can be classified into two categories. (1) those caused by a deficit of nutritional factors, and (2) those resulting from mechanical effects, with the qualification that the first could result from the second. Degenerative changes found in the hair cells of the organ of Corti, in the epithelium of the macula and that of its cristae of the semicircular canals, in the stria vascularis and in the ganglionic cells in the spiral ganglion (not always demonstrable) can be explained either by a dysproteinemia resulting from a primary pathological process involving the entire organism or from nutritional defect resulting from local ischemia caused by increased pressure within the endolymphatic space.

Other pathologic findings such as distention and rupture of Reissner's membrane, distension of the whole endolymphatic system with obliteration of the perisacal space which normally contains a rich blood supply result from the increased pressure in the endolymphatic space, etc. Excessive endolymphatic pressure which causes local ischemia leads, in turn, to tissue hypoxia, degenerations, and eventually to atrophy this might also be the mechanism of the atrophy of sacal duct followed by obliteration of the vestibular aqueduct (Clemis & Salvassori, 1968).

The chances for the restitution of the atrophic hair cells in organ of Corti to a normal function in the inner ear are minimal or none when morphologic changes have advanced into the irreversible state this applies also to the rupture of Reissner's membrane (some authors maintain that such repeated rupture and healing of Reissner's membrane, marks the remissions and relapses of Menière's disease (Lawrence & McCabe, 1959)) and obliteration of the perisacal space (Shambaugh ascribes etiological value of the loss of capillary network in the perisacal connective tissue (1966)). If the organic changes of the endolymphatic system is still in a reversible stage, a properly selected therapeutic management will arrest the progress of the disease or induce a partial or complete remission, regardless of the duration of the disease. Unfortunately since information on morphologic changes is not available to the clinician, it is impossible to predict the end result of therapy

An endocrinological survey of 250 patients with Menière's disease (Table II) has revealed deficiency in th.h. in one form or another in 89.2% of all cases studied. It is therefore suggested that the th.h. deficiency led to a general deficiency of protein formation and to an inadequate function of hyaluronidase. A state of molecular disease of proteins coexists in other organs but the degree of dysproteinemia is either not sufficiently advanced, or the methods used are not sensitive enough to demonstrate anatomic changes and/or dysfunction of other organs.

The hypometabolic states which contribute to a low titre of hyaluronidase in the endolymph are associated with other factors which might secondarily influence the depolymerizing action of hyaluronidase. For example a deficit of th.h. facilitates invasion of the organism by various living pathogens. Hyaluronidases of bacterial or fungal origin (also called "spreading factor" (Duran-Reynolds 1929)) may act as an antigen and induce the formation of specific antibodies directed against the bacterial hyaluronidases. A subsequent Ag/Ab reaction would immobilize the bacterial hyaluronidase. By cross-specificity these same bacterial anti hyaluronidases may act upon the organism's own hyaluronidase and block its depolymerizing action. Pathogens which exist in the body in an apparent state of physiological coexistence with the host also may produce toxins which act as enzymic inhibitors. These enzymic inhibitors may invade the organism in *sub-toxic doses* without causing a local reaction at the portal of their entry. Constant flooding of the organism by enzymic inhibitors from subclinically involved organs is often not appreciated either by the patient or by his physician because the cause and effect relationship is not apparent, for instance between Menière's disease and chronic prostatitis or chronic cervicitis.

In our series of 250 patients with Menière's disease, the incidence of *attenuated chronic* infections was 91.2% (Table III). About half of these were prostatic or vaginal infections. Control of the infections by specific anti-bacterial or anti fungal agents along with hormonal replacement resulted in remission of the Menière's disease which promptly relapsed when local or systemic acute infectious agents were discontinued. Hormonal replacement in these patients was insufficient for control of the disease.

Bacterial and fungal toxins are not the sole inhibitors which may affect the depolymerization of mucopolysaccharides by hyaluronidase. A group of organic and inorganic compounds, either penetrating the organisms from without or originating inside the body *may also* interact with and inhibit the depolymerizing action of hyaluronidase. clinicians, (Cawthorn, 1947 Shambaugh, Jr 1959 Godlowski, 1952). In evaluating any type of episodic vertigo, a careful study of all potential sources of infection is essential. Throat, nasal and paranasal cavities, mouth, prostate, vagina, cervix and adnexa, may harbor *organisms* the products of which inactivate hyaluronidase and affect osmotic equilibrium in the entire organism, even though the presenting clinical symptoms may be limited to endolymphatic hypertension. The pathogens in the suspected areas, therefore, should be routinely investigated and their sensitivities toward antibiotics determined.

Any coexisting or suspected allergic hypersensitivities, particularly food allergy should be investigated because the products of allergic proteolysis (toxic catabolites) may also act as inhibitors of the depolymerizing action of hyaluronidase. Offending antigens may be detected by careful history intracutaneous diagnostic tests, cytotoxin food tests (Rinkel et al. 1951 Rinkel, 1962 and 1963 Rinkel et al. 1964) elimination diets with subsequent feedings" (Randolph, 1962) or by Intracutaneous Food Provocative Tests (Rinkel, 1962, Rinkel et al., 1964). For details see Chapter 28, *Allergy and Anaphylaxis as Metabolic Error* (Godlowski, 1962) and comprehensive summary in Tables IV and V

IMMUNO-METABOLIC THERAPY OF MENIERE'S DISEASE

The therapeutic aims in Menière s disease is the restoration of the osmotic pressure within the endolymphatic space to its physiological values. Only one factor can control the increased hydrodynamic and hyperosmotic pressures of the endolymph, that is restitution of the depolymerizing action of hyaluronidase. Retention of water and electrolytes are secondary factors which can be controlled by the specific action of the hydrophylic mucopolysaccharides. However three subsidiary factors may aggravate the primary etiologic mechanism which may on rare occasions, play a primary role in the rational treatment of Menière s disease

(1) excretory insufficiency of the endolymphatic sac with coexisting obliteration of sacal duct,

(2) fluctuations in the driving pressure within the arterial end of the capillary bed in stria vascularis, or reduction of the osmotic pressure of the blood plasma at the venous end;

(3) capillaritis involving the capillary net work in the stria vascularis.

Keeping in mind the main factors controlling the flow of endolymph and endolymphatic pressure, the therapeutic approach to endolymphatic hydrops runs along two lines:

(1) Elimination of the etiological factors which are responsible for *molecular disease of proteins* and the consequent hyperosmolality of the endolymph.

(2) Decompression of endolymphatic hypertension by medical and/or surgical procedures.

I. Etiological therapy of Menière's disease

Since Menière s disease is a local expression of a molecular disease of proteins involving the whole organism therapeutic efforts should be concentrated primarily upon the correction of the metabolic error Only then will reduction of endolymphatic hypertension obtained by surgical or pharmacological methods have a reasonable chance of staying in permanent remission. There are no specific therapeutic agents, save hyaluronidase, which selectively act upon the hyaluronate mucopolysaccharides. Only hyaluronidase depolymerizes the water-binding property of hyaluronate mucopolysaccharides within the endolymphatic system. So far therapeutic attempts to use hyaluronidase directly to reduce pressure within the endolymphatic space have failed completely (Marco *et al.*, *1956*). Deposited hyaluronidase in the middle ear of normal guinea pigs with the hope that it would diffuse into the endolymph was bound to *fail*

Clinical Management of Menière's Disease

INTRODUCTION

Clinical management of Menière's disease consists of (1) *diagnostic determination* of the primary cause which has initiated the hyper tension in the inner ear (2) administration of *specific therapy*

In most cases of Menière's disease two or three avenues must be employed simultane ously in the management of the patient in order to obtain maximal therapeutic success. The rational management of Menière's disease requires a close coordination of at least two specialists the otologist who possesses the informative diagnostic armamentarium and surgical skill necessary for a mechanical de compression or for destructive surgery but who is usually not sufficiently experienced to interpret the immunological and metabolic er rors or to administer the endocrine and meta bolic agents necessary to correct the primary molecular disease Endolymphatic hydrops is an immuno-metabolic disease just as is e.g diabetic retinopathy Both these conditions must be managed by a physician with a wide and profound immuno-metabolic background and experience who cooperates with the otologist or ophthalmologist respectively in order to maintain the patient in remission The qualified internist usually is not sufficiently skilled in diagnostic and therapeutic otologic procedures to differentiate the type of inner ear disease present or to evaluate objectively the progression or the remission of the disorder The general practitioner is neither equipped for otologic diagnosis nor for im muno-endocrinologic evaluation, although he is usually competent to carry out the therapy outlined by his colleagues.

DIAGNOSTIC EVALUATION OF MENIERE S DISEASE

The history if taken carefully may in many instances, reveal a connection in time between the onset of manifestations of endolymphatic hypertension and an infection. Mild infection especially could have been as consequential in precipitating endolymphatic hydrops as the severe forms. Not unusually "mild colds or "sore throats, cystitis or cervicitis indicate the avenue along which the diagnostic investigations should proceed Physical examination must include a complete otological study such as the hearing loss, functional otological tests consisting of determination of air and bone conductions, speech discrimination Bekesy audiometry caloric tests, and electronystagmographic. Study of labyrinthine function on the primary examination determines the form and the degree of the disease on which progress of the therapy is assessed

Further diagnostic studies are performed according to the immunometabolic survey as outlined in Volume 2 "Allergy and Anaphylaxis as Metabolic Error (Godlowski 1962) and summarized in Tables IV and V Proteins, carbohydrates, fat water and electrolytes must be investigated from as many angles as are available Particular attention must be paid to the thyroid profile keeping in mind the basic rule that a single test for thyroid function cannot satisfactorily evaluate the th h status even if a positive result is obtained.

The importance of bacterial toxins and antigens from acute or chronic inflammatory foci in precipitating endolymphatic hypertension has been strongly emphasized by many

exchange by the products of inflammation. Inflammations of bacterial, viral, and fungal origin, or those of allergic toxic, or physicochemical nature, possess one metabolic mechanism in common, i.e. liberation of products of incomplete catabolism of proteins which possess a variety of inhibiting effects on the enzymic systems. Each type of inflammation, however requires a specific therapeutic approach.

A. *Administration of broad-spectrum antibiotics or chemotherapeutic compounds* selected, if possible, by sensitivity tests in vitro The effective dose of the selected antibiotic should be given for at least seven to fourteen days, thereafter a similar dosage should be repeated during periods of seven days each month for six to twelve consecutive months. In resistant infections, combinations of antibiotics with sulfa compounds may circumvent mutation with the formation of new strains of pathogens resistant to the antibiotics being given.

B *Administration of local antiseptics to actively infected organs or those which are harboring them* Latent infections existing in organs which are regarded as "non-sterile" may create a hazard to patients with endolymphatic hydrops. Such infections are most apt to exist in mouth, throat, prostate vagina, or rectum. They require continuous control by an antiseptic which will restrict the growth of pathogens without obviously affecting the tissues of the host. I use Phenex Antiseptic® (Phenex Laboratory Chicago Illinois) as the antiseptic of choice for the following reasons

(1) Phenex Antiseptic does not damage the tissues of the host, but rather stimulates production of normal granulation tissue, and speeds up epithelization of ulcers and wounds

(2) it is anesthetic, analgesic, antipruritic, and deodorizing;

(3) it penetrates rapidly into the deeper layers of skin and mucous membranes,

(4) it is available in forms applicable to many infected organs, either as a solution, a lotion, an ointment, a nasal or throat spray or a rectal or vaginal suppository

(5) it possesses a wide spectrum of bactericidal and fungicidal effects.

In my patients with endolymphatic hypertension (see Table III) a chronic asymptomatic prostatitis was frequently found. Chronic prostatitis with or without hypertrophy is frequently found in men over forty Mild infections of the vagina, cervix and adnexa were also frequently found in women with Menière's disease. These infections must be energetically treated. Unfortunately the role of infection in the pathogenesis and therapy of endolymphatic hypertension is rarely sufficiently appreciated or given adequate therapeutic management by otologists.

C. *Anti-inflammatory steroids (glucocorticoids) as non-specific adjunctive therapy* The therapy with anti-inflammatory steroids should be initiated as soon as the diagnosis of endolymphatic hypertension is established and continued as long as the acute symptoms persist These steroids must be given along with other stress-relieving agents such as antimicrobial drugs when infections are present, and with other items of immunometabolic management. When the initial symptoms begin to subside the dosage of the steroid is gradually reduced while the other therapeutic agents are maintained. In moderately severe cases of endolymphatic hypertension, the average duration of steroid therapy is six to ten weeks. During this time the patient must be carefully supervised, at weekly intervals or oftener for side-effects such as cardiovascular embarrassment progressing osteoporosis, activation of peptic ulcer or other sources of gastrointestinal bleeding. In refractory cases, a maintenance dose of steroids may be required.

Prednisolone or its derivatives, is the preferable form of steroid because its sodium-retaining effect is less pronounced, and its anti-inflammatory effect is more marked than naturally occurring cortisol or hydrocortisol. The initial dose of prednisolone for adults

because the osmotic pressure within a normal endolymphatic system is higher *than that outside* the round window. Still less *chance of* success had the attempt to reduce the endolymphatic pressure in human endolymphatic hydrops by the deposition of hyaluronidase outside the round window (Wölger 1942) because *the osmotic pressure of the endolymph* in endolymphatic hydrops is much higher than it is under normal conditions so that the desired diffusion of hyaluronidase into endolymph is obviously impossible. In my own experience, intravenous infusion of five million units of hyaluronidase ("Wydase" Wyeth Company) during a six hour period resulted in the elimination of all four intractable symptoms (deafness vertigo tinnitus, and fullness *in ears) only for* the initial hour. Soon all manifestations returned to their previous severity and remained unchanged for the whole *period of* therapy during the next ten days *(Godlowski unpublished)*. Most likely the failure of intravenous therapy with hyaluronidase was caused by:

(1) a rapidly rising anti hyaluronidase titer in the blood inactivating the circulating exogenous hyaluronidase

(2) rapid distribution of the infused hyaluronidase through the extra-cellular compart*ments of the entire organism reducing the* circulating hyaluronidase to an insignificant quantity except for the first few minutes when the penetration of the endolymphatic space via the stria vascularis did occur (Meyer et al. 1936)

Because the diagnostic methods in use at present fail to elucidate the primary cause of the pathology in most cases of endolymphatic hypertension the clinical management must therefore be

(1) multilateral, encompassing all the possible pathogenic factors discussed above

(2) long term sometimes extending over the patient's whole life

The possibility that the symptoms of endolymphatic hydrops must be controlled for life has to be kept in mind by both the physician and the patient. Often both physician (particularly the otologist) and patient are *over-anxious* to obtain immediate relief which may oc*cur only in* exceptional instances. Sometimes instances of acute or subacute infections, allergic hypersensitivity reactions, or exposure to *enzymatic inhibitors*, when promptly recognized and *effectively treated will* restore the osmotic balance in the endolymphatic *space within* a few days. A complete perman*ent remission* can occur only if an anabolic supplement is adequately provided. In contrast to such cases, a spectacular improvement after surgery (chiefly in the vertiginous attacks, but less *often* in hearing and tinnitus) may restore the patient to a more or less *normal* life without eliminating the disease. These postoperative patients with a complete or partial remission still require continuous therapy otherwise they will experience a relapse of symptoms. It is often difficult, in these circumstances, to convince the patient, who is now without obvious complaints or the surgeon who is credited with the spectacular re*mission that the primary metabolic error* is still present and should be treated.

Immuno-metabolic therapy of endolymphatic hypertension consists of four items of equal importance. In intractable cases all four agen*cies should be employed concurrently*

(1) disposal of inflammatory stress

(2) supplementation with anabolic agents

(3) suppression of the property of hypothalamus to redistribute those pathologic stimuli which derive from the target organs

(4) allergic hyposensitization using optimal dosage technique

The details of this multilateral therapy are presented in Part VI of Volume 2 of *Allergy and Anaphylaxis as Metabolic Error* (Godlowski, 1965) however a brief summary of the management is presented below in Tables IV and V

1 *Disposal of the inflammatory stress*

By inflammatory stress is meant the inhibition of the anabolic and catabolic phases of energy

exchange by the products of inflammation. Inflammations of bacterial viral, and fungal origin, or those of allergic toxic, or physico-chemical nature, possess one metabolic mechanism in common, i.e. liberation of products of incomplete catabolism of proteins which possess a variety of inhibiting effects on the enzymic systems. Each type of inflammation, however requires a specific therapeutic approach.

A. *Administration of broad-spectrum antibiotics or chemotherapeutic compounds* selected, if possible, by sensitivity tests in vitro The effective dose of the selected antibiotic should be given for at least seven to fourteen days; thereafter a similar dosage should be repeated during periods of seven days each month for six to twelve consecutive months. In resistant infections, combinations of antibiotics with sulfa compounds may circumvent mutation with the formation of new strains of pathogens resistant to the antibiotics being given.

B. *Administration of local antiseptics to actively infected organs or those which are harboring them* Latent infections existing in organs which are regarded as "non-sterile" may create a hazard to patients with endolymphatic hydrops. Such infections are most apt to exist in mouth, throat, prostate, vagina, or rectum. They require continuous control by an antiseptic which will restrict the growth of pathogens without obviously affecting the tissues of the host I use Phenex Antiseptic® (Phenex Laboratory Chicago Illinois) as the antiseptic of choice for the following reasons.

(1) Phenex Antiseptic does not damage the tissues of the host, but rather stimulates production of normal granulation tissue, and speeds up epithelization of ulcers and wounds,

(2) it is anesthetic, analgesic antipruritic, and deodorizing;

(3) it penetrates rapidly into the deeper layers of skin and mucous membranes;

(4) it is available in forms applicable to many infected organs, either as a solution, a lotion, an ointment, a nasal or throat spray or a rectal or vaginal suppository

(5) it possesses a wide spectrum of bactericidal and fungicidal effects.

In my patients with endolymphatic hypertension (see Table III) a chronic asymptomatic prostatitis was frequently found. Chronic prostatitis with or without hypertrophy is frequently found in men over forty Mild infections of the vagina, cervix and adnexa were also frequently found in women with Menière's disease. These infections must be energetically treated. Unfortunately the role of infection in the pathogenesis and therapy of endolymphatic hypertension is rarely sufficiently appreciated or given adequate therapeutic management by otologists.

C. *Anti-inflammatory steroids (glucocorticoids) as non-specific adjunctive therapy* The therapy with anti-inflammatory steroids should be initiated as soon as the diagnosis of endolymphatic hypertension is established, and continued as long as the acute symptoms persist. These steroids must be given along with other stress-relieving agents such as antimicrobial drugs when infections are present, and with other items of immunometabolic management. When the initial symptoms begin to subside, the dosage of the steroid is gradually reduced while the other therapeutic agents are maintained. In moderately severe cases of endolymphatic hypertension, the average duration of steroid therapy is six to ten weeks. During this time the patient must be carefully supervised, at weekly intervals or oftener for side-effects such as cardiovascular embarrassment, progressing osteoporosis, activation of peptic ulcer or other sources of gastrointestinal bleeding. In refractory cases, a maintenance dose of steroids may be required.

Prednisolone or its derivatives, is the preferable form of steroid because its sodium retaining effect is less pronounced, and its anti-inflammatory effect is more marked than naturally occurring cortisol or hydrocortisol. The initial dose of prednisolone for adults

because the osmotic pressure within a normal endolymphatic system is higher than that outside the round window Still less chance of success had the attempt to reduce the endolymphatic pressure in human endolymphatic hydrops by the deposition of hyaluronidase outside the round window (Wölger 1942) because the osmotic pressure of the endolymph in endolymphatic hydrops is much higher than it is under normal conditions so that the desired diffusion of hyaluronidase into endolymph is obviously impossible. In my own experience, intravenous infusion of five million units of hyaluronidase ("Wydase Wyeth Company) during a six hour period resulted in the elimination of all four intractable symptoms (deafness vertigo tinnitus, and fullness in ears) only for the initial hour Soon all manifestations returned to their previous severity and remained unchanged for the whole period of therapy during the next ten days (Godlowski unpublished) Most likely the failure of intravenous therapy with hyaluronidase was caused by

(1) a rapidly rising anti-hyaluronidase titer in the blood inactivating the circulating exogenous hyaluronidase

(2) rapid distribution of the infused hyaluronidase through the extra-cellular compartments of the entire organism reducing the circulating hyaluronidase to an insignificant quantity except for the first few minutes when the penetration of the endolymphatic space via the stria vascularis did occur (Meyer et al. 1936)

Because the diagnostic methods in use at present fail to elucidate the primary cause of the pathology in most cases of endolymphatic hypertension the clinical management must therefore be

(1) multilateral, encompassing all the possible pathogenic factors discussed above

(2) long-term sometimes extending over the patient s whole life.

The possibility that the symptoms of endolymphatic hydrops must be controlled for life has to be kept in mind by both the physician and the patient. Often both physician (particularly the otologist) and patient are over-anxious to obtain immediate relief which may occur only in exceptional instances. Sometimes instances of acute or subacute infections, allergic hypersensitivity reactions, or exposure to enzymatic inhibitors, when promptly recognized and effectively treated will restore the osmotic balance in the endolymphatic space within a few days. A complete permanent remission can occur only if an anabolic supplement is adequately provided. In contrast to such cases, a spectacular improvement after surgery (chiefly in the vertiginous attacks, but less often in hearing and tinnitus) may restore the patient to a more or less normal life without eliminating the disease These postoperative patients with a complete or partial remission still require continuous therapy otherwise they will experience a relapse of symptoms. It is often difficult, in these circumstances, to convince the patient who is now without obvious complaints, or the surgeon who is credited with the spectacular remission that the primary metabolic error is still present and should be treated

Immuno-metabolic therapy of endolymphatic hypertension consists of four items of equal importance in intractable cases all four agencies should be employed concurrently

(1) disposal of inflammatory stress,

(2) supplementation with anabolic agents

(3) suppression of the property of hypothalamus to redistribute those pathologic stimuli which derive from the target organs,

(4) allergic hyposensitization using "optimal dosage technique

The details of this multilateral therapy are presented in Part VI of Volume 2 of *Allergy and Anaphylaxis as Metabolic Error* (Godlowski 1965) however a brief summary of the management is presented below in Tables IV and V

1 *Disposal of the inflammatory stress*

By inflammatory stress is meant the inhibition of the anabolic and catabolic phases of energy

tion of T3 upon the endogenous output of TSH (Godlowski, 1965). The initial dosage of T4 is 0.05 mg or less once daily but gradual increase in dosage to the level of tolerance may be required. The duration of therapy with thyroid hormone depends on the *form* of thyroid hormone deficiency: *primary hypothyroidism* requires permanent administration of a maintenance dose for life (Godlowski 1965). In children and young adults, the dosage of th.h. is more liberal nevertheless, strict supervision is always indicated. T3 up to 25 mcg three times daily along with T4 up to 0.2 mg, or more, is the usual starting dose.

In *secondary hypothyroidism* TSH (5 to 10 units) or crude anterior pituitary extract (1 ml) is initially administered in weekly intramuscular injections together with other parenterally administered anabolic agents. When initial manifestations subside, the TSH injection should be extended to monthly intervals or as is required.

(7) *Male and female sex hormones.* Male hormone has a strong anabolic property in both sexes however in women it may have an untoward influence on the menstrual cycle or produce undesirable virilizing side-effects. Male hormone is given as *testosterone* preferably in an aqueous suspension to adult males in doses of from 25 to 50 mg injected intramuscularly once or twice weekly using the same syringe containing the other anabolic agents. In adult females, the dosage of testosterone should fluctuate between 5 and 25 mg in weekly injections mixed in the same syringe *with estrogens (10 000 to 20 000 units)* but avoiding the hormones in the week of expected menstruation. In men, estrogens are given in amounts which may fluctuate between 5 000 and 10 000 units a week. Feminizing effects or sexual impotence may occasionally become a side-effect of this therapy in which case the estrogens must be completely omitted. Adolescent and preadolescent children of both sexes are treated with sex hormones by an identical technique: testosterone 5 to 10 mg with estrogens with 5 *to* 10 000 units are injected intramuscularly weekly with other anabolic agents mixed in the same syringe. If masculinizing or feminizing effects complicate the therapy the dosage of the heterosexual hormone should be reduced or eliminated, and the isosexual hormone should be increased. Precosity occasionally may occur which, however spontaneously disappears on discontinuation of sex hormone therapy

The oral or injectable anabolic steroids (derivative of sex hormones) can replace sex hormones, as they fully retain the anabolic property but the sexual effects are grossly reduced these are: Nilevar®" Searle and Company "Winstrol®" Winthrop Laboratories, Durabolin®" Organon, Inc. etc. They can be used in both males and females, adults and children.

B. *Anabolic vitamin supplement* Vitamin B-Complex with ascorbic acid such as Vicam®" Marion Laboratories, Folbesyn®" Lederle Company: Berocca with C®" Roche Company: etc. are routinely given intramuscularly once a week mixed with other anabolic agents with addition of 1 ml 2% Pontocaine or any local anesthetic. Oral administration of vitamins in patients *of the older age* group is not recommended because of the frequency of malabsorption from the gastrointestinal tract secondary to senile atrophy and amyloidosis of the intestinal mucosa *and* pancreas (Schwartz, 1965). These changes are often found to be associated with dysproteinemia and tend to prevent utilization of ingested vitamins. Lipoflavonoids *supplemented with the vitamins* of the rest of B-complex and Vitamin C when applied as a sole therapy of endolymphatic hypertension has been shown (Williams, 1963) to be effective only in selected *forms* of Ménière's disease (Shambaugh, 1963 Derlacki, 1965). The rationale of large doses of anabolic vitamins in the therapy of endolymphatic hypertension is based on their mediating role in the anabolic action of hormones and enzymes which participate in the formation of proteins.

C. *Anabolic mineral supplement* Minerals

should be 5 mg three times daily only in rare instances should the daily dosage exceed 30 mg If side-effects appear during this short period of therapy the dosage must be drastically reduced by at least, two-thirds, and anabolic agents (see below) applied in double dosage If cardiovascular manifestations of a more serious nature appear or bleeding from the gastrointestinal tract occurs, steroids must be discontinued immediately and appropriate therapy instituted (Godlowski 1965)

Since the exact mechanism of cortisol action is not finally established the rationale for steroid therapy in endolymphatic hypertension is also not clear The available evidence indicates that normal proteolysis may be effectively enhanced by cortisol (Godlowski 1952) It is believed that normal proteolysis can be promoted by cortisol and that toxic catabolites, which inhibit hyaluronidase are catabolized to non toxic derivatives. If this is true, the depolymerizing action upon the hyaluronate mucopolysaccharides of the hyaluronidase within the endolymphatic space (and by that matter anywhere else in the body) may be restored and so the hyperosmolality of the endolymph thereby reduced

2. *Supplementation with anabolic agents*

Supplementation of the erratic metabolism with anabolic agents is a powerful instrument in the treatment of endolymphatic hypertension Anabolic agents consist of anabolic hormones, anabolic vitamins and minerals essential proteins although not anabolic agents per se represent the building material from which new proteins are formed therefore they are included in the anabolic supplementation therapy of endolymphatic hypertension.

A *Anabolic hormones* Supplementation of abnormal metabolism with anabolic hormones is accomplished with thyroid hormones and male and female sex hormones hormones which stimulate their production although non-anabolic per se (TSH FSH and chorionic gonadotropins) are briefly discussed here because they exhibit an anabolic effect as an end result.

(1) *Thyroid hormones.* Thyroid hormones are divided according to their physiological actions

(a) *a short-acting form* L-tri-iodothyronine (T3 Cytomel® *Smith Kline* and French Laboratory) supplied in tablets containing 5 mcg and 25 mcg respectively

(b) *a long-acting form* levorotary sodium tetraiodothyronine (thyroxine T4—Synthroid® *Flint Laboratory*) *in tablets* containing 0 025 0 05 0 1 0.15 0.2 0.3 0 4 and 0.5 mg—"Letter' ® Armour Company (in similar dosage), or its analogues

(c) *a long-acting dextrotary sodium tetraiodothyroxine* (D-T4—Choloxin® Flint Laboratory) in tablets containing 2 and 4 mg

Desiccated thyroid in any form is a less desirable way of medication because thyroglobulin (or any iodinated tyrosine compound) acts only if it is converted into T4 by specific hydrolysis which is often faulty furthermore, there are cases on record of antibody formation against thyroglobuline during treatment with desiccated thyroid tablets (Godlowski 1965) Two forms of thyroid hormone medication have recently appeared on the market "Thyrolar ® (Armour Company) and Euthroid ® (Chilcott Warner Laboratory) Both forms contain combination of T3 with T4 in various proportions. The advantage of such combination is that one tablet contains both forms of thyroid hormone short and long acting. The disadvantage, on the other hand of such a combination is that the combination of the two forms of thyroid hormone eliminates the therapeutic maneuverability if one of them is not well tolerated or is not required.

The dosage of T3 in adults over forty years is 5 μg three times daily if well tolerated, and the larger quantities are required for the therapeutic effects, then a gradual step-up in dosage to the level of tolerance may be indicated. In the same age group, T4 is given along with T3 to prevent the suppressive ac

tion of T3 upon the endogenous output of TSH (Godlowski, 1965). The initial dosage of T4 is 0.05 mg or less once daily but gradual increase in dosage to the level of tolerance may be required. The duration of therapy with thyroid hormone depends on the *form of thyroid hormone deficiency*: *primary hypothyroidism* requires permanent administration of a maintenance dose for life (Godlowski, 1965). In children and young adults, the dosage of th.h. is more liberal, nevertheless, strict supervision is always indicated. T3 up to 25 mcg three times daily along with T4 up to 0.2 mg, or more, is the usual starting dose.

In *secondary hypothyroidism* TSH (5 to 10 units) or crude anterior pituitary extract (1 ml) is initially administered in weekly intramuscular injections together with other parenterally administered anabolic agents. When initial manifestations subside, the TSH injection should be extended to monthly *intervals*, or as is required.

(2) *Male and female sex hormones.* Male hormone has a strong anabolic property in both sexes, however in women it may have an untoward influence on the menstrual cycle or produce undesirable virilizing side-effects. Male hormone is given as *testosterone* preferably in an aqueous suspension to adult males in doses of from 25 to 50 mg injected intramuscularly once or twice weekly using the same syringe containing the other anabolic agents. In adult females, the dosage of testosterone should fluctuate between 5 and 25 mg in weekly injections mixed in the same syringe with estrogens (10 000 to 20 000 units) but avoiding the hormones in the week of expected menstruation. In men, estrogens are given in amounts which may fluctuate between 5 000 and 10 000 units a week. Feminizing effects or sexual impotence may occasionally become a side-effect of this therapy in which case the estrogens must be completely omitted. Adolescent and preadolescent children of both sexes are treated with sex hormones by an identical technique: testosterone 5 to 10 mg with estrogens with 5 to 10 000 units are injected intramuscularly weekly with other anabolic agents mixed in the same syringe. If masculinizing or feminizing effects complicate the therapy the dosage of the heterosexual hormone should be reduced or eliminated, and the isosexual hormone should be increased. Precocity occasionally may occur which, however spontaneously disappears on discontinuation of sex hormone therapy.

The oral or injectable anabolic steroids (derivative of sex hormones) can replace sex hormones, as they fully retain the anabolic property but the sexual effects are grossly reduced these are Nilevar®" Searle and Company "Winstrol®" Winthrop Laboratories; Durabolin® Organon, Inc. etc. They can be used in both males and females, adults and children.

B. *Anabolic vitamin supplement.* Vitamin B-Complex with ascorbic acid such as "Vicam®" *Marion Laboratories*, "Folbesyn®" Lederle Company Berocca with C®" Roche Company etc. are routinely given intramuscularly once a week mixed with other anabolic agents with addition of 1 ml 2% Pontocaine or any local anesthetic. Applied in the management of Menière's disease

	Diagnostic procedure	
1st day	Nonfasting patient	(a) History and physical examination (b) Cytotoxic food tests in a.m. (c) Inhalant skin tests. (1) vertical, (2) linear if required (d) Provocative skin tests in p.m. of positive Ag-foods found in cytotoxic tests and per history
2nd day	Fasting patient	( ) Cytotoxic food tests in a.m. (b) Metabolic panel with blood enzyme studies and X-ray of GI tract (c) Provocative skin testing of positive tests found in fasting cytotoxic tests
3rd day	After Ag-foods (feeding with positive foods and known from history in groups of five foods)	(a) Cytotoxic food tests of fed foods in a.m. (b) Provocative skin tests of fed foods in p.m.
4th day	After Ag-foods	Continuation if required as in 3rd day
5th day	After Ag-foods	Continuation if required as in 3rd day
6th day	Nonfasting	Résumé and outline of therapy

Ag-food. Food which causes positive reaction in one form of testing.

thereby initiate primarily or aggravate secondarily the existing pathology. Therefore the allergic reaction should be controlled whether it is the primarily precipitating factor in endolymphatic hypertension or whether it contributes secondarily.

The specific therapy of allergic reactions consist of the determination of the specific antigen and its injection in optimal dosage for hyposensitization, that is for the prevention of toxic proteolysis. The optimal dose is determined by skin titration (Rinkel, 1962) with the specific antigen in which the end-point constitutes the required initial dose. The details of the basic principles and technique of the therapy of allergic states are outlined in Parts V and VI of Volume 2 of *Allergy and Anaphylaxis as Metabolic Error* (Godlowski, 1965), and briefly summarized in Tables IV and V.

II. Symptomatic management of endolymphatic hypertension

Symptomatic therapy of endolymphatic hypertension consists in securing medical or surgical relief of symptoms derived from endolymphatic hypertension. Internists and surgeons who use these therapeutic methods claim no more than a control of the clinical manifestations of inner ear disease. Symptomatic relief of endolymphatic hypertension must, therefore, be regarded as an adjunct to the "etiological" therapy outlined in the previous paragraphs.

Symptomatic therapy of endolymphatic hypertension consists of (*a*) decompression of the endolymphatic hydrops, and (*b*) destruction of the inner ear.

Decompression of the endolymphatic hypertension in the management of endolymphatic hydrops

Decompression of the endolymph in hydrops may be accomplished either by pharmacologic or surgical means. Successful decompression assists in the recovery of the damaged inner ear organs. Correction of the dysproteinemia makes the beneficial effects of decompression more lasting. Therefore, *the two techniques should be applied concurrently in the rational management of endolymphatic hyperten-*

which participate in the activation of the enzymic reactions (as coenzymic factors) are also regarded as anabolic agents therefore their adequate supply orally or parenterally belong to the management of endolymphatic hypertension Mg Ca Mn Fe Fe and Co are best assimilated in the chelated form which guarantees their passage through the intestinal mucosa in an active form Minerals for oral administration should be complexed with ascorbic acid which acts as the ligand enteric coating of the tablets is effective in guaranteeing their passage through *stomach Such tablets are available on the* market as Hyalex®" and "Magnesium Plus®" (Pharmacal Company West Chicago Illinois)

D *Essential proteins supplement* In the management of endolymphatic hypertension a diet high in animal proteins will supply building material for the formation of the organisms own proteins. Essential proteins are recommended in amounts of 2 to 4 gm per kilo per 24 hours in forms of meat poultry fish milk and milk products, eggs, and the like These proteins however contain high animal fat which might be contraindicated in cases of endolymphatic hypertension associated with high blood cholesterol. In such an event the high protein diet should then be devoid of animal fats (well-done meats, skim milk egg whites, etc) or to administer "Questran® Meade Johnson (cholesteramin) which acts as a resin absorbing the dietary fats on the molecular surface (Godlowski 1965)

3 Hypothalamic suppression

Hypothalamic suppression by psychotropic medication oftentimes has a strategic value in the successful management of endolymphatic hypertension The hypothalamus is the central distributor of all stimuli penetrating the organism from the outside or generated within the body Stimuli which originate in various organs such as the liver gallbladder stomach, and duodenum might be projected to the inner ear and initiate inner ear manifestations such as vertigo (called sometimes vertigo stomachialis) tinnitus or nausea, thereby mimicking the symptoms of primary ear pathology Conversely primary ear diseases such as endolymphatic hypertension may be projected upon the subdiaphragmatic organs, and cause nausea and vomiting, which is also often associated with vertigo originated from the endolymphatic system.

Tranquilizing agents of a *central relaxant* and *hypothalamic suppressant* type block the redistribution of stimuli received from target organs. A central relaxant such as meprobamates or hypothalamic suppressants such as derivatives of phenothiazine and phenylmethane may be used concurrently with the other therapeutic agents included in the management of endolymphatic hypertension. For example there are readily available combination of anti-inflammatory steroid with hypothalamic suppressant such as "Ataraxoid® (Pfizer Laboratory) tablets containing either 2.5 or 5 mg of prednisone together with 10 mg of "Atarax® (hydroxizine HCl) The reader may find in the quoted references the details of administration of psychotropic drugs in reference Godlowski (1965)

4 Management of allergic reactions associated with endolymphatic hypertension

In our series the incidence of allergic reactions in patients with endolymphatic hypertension were around 67.2% (Table III) This need not necessarily be interpreted that the aural pathology is caused by hypersensitivity or that endolymphatic structures such as stria vascularis are directly involved in the allergic reactions, but hypersensitivity is, with little doubt one of the most common causes of endolymphatic hypertension The products of toxic proteolysis in the inner ear or elsewhere in the body which constitute the basic mechanism of allergic reaction (Godlowski 1962), may primarily or secondarily affect the depolymerizing action of hyaluronidase and influence the circulation of the endolymph

Ag-food. Food which causes positive reaction in one form of testing.

thereby initiate primarily or aggravate secondarily the existing pathology. Therefore the allergic reaction should be controlled whether it is the primarily precipitating factor in endolymphatic hypertension or whether it contributes secondarily.

The specific therapy of allergic reactions consist of the determination of the specific antigen and its injection in optimal dosage for hyposensitization, that is for the prevention of toxic proteolysis. The optimal dose is determined by skin titration (Rinkel, 1962) with the specific antigen in which the end-point constitutes the required initial dose. The details of the basic principles and technique of the therapy of allergic states are outlined in Parts V and VI of Volume 2 of *Allergy and Anaphylaxis as Metabolic Error* (Godlowski, 1965), and briefly summarized in Tables IV and V.

II. Symptomatic management of endolymphatic hypertension

Symptomatic therapy of endolymphatic hypertension consists in securing medical or surgical relief of symptoms derived from endolymphatic hypertension. Internists and surgeons who use these therapeutic methods claim no more than a control of the clinical manifestations of inner ear disease. Symptomatic relief of endolymphatic hypertension must, therefore, be regarded as an adjunct to the "etiological" therapy outlined in the previous paragraphs.

Symptomatic therapy of endolymphatic hypertension consists of (*a*) decompression of the endolymphatic hydrops, and (*b*) destruction of the inner ear.

Decompression of the endolymphatic hypertension in the management of endolymphatic hydrops

Decompression of the endolymph in hydrops may be accomplished either by pharmacologic or surgical means. Successful decompression assists in the recovery of the damaged inner ear organs. Correction of the dysproteinemia makes the beneficial effects of decompression more lasting. Therefore, *the two techniques should be applied concurrently in the rational management of endolymphatic hyperten-*

Table V *Therapy of food allergy*

Applied to patient with Menière's disease with positive food allergy

1 Patients with food positive in all four groups of tests (+ + + +)
(a) Elimination of Ag-foods, next if controlled gradual rotation Ag-food with sublingual drops if digestive and/or metabolic error is controlled
(b) Digestive enzymes in large doses orally with each meal (supplemented with sublingual drops or subcutaneous injections if carrier or enzyme itself is made from animals positive in testing
(c) Correction of metabolic and/or organic error in GI tract
(d) Drops or subcutaneous injection of Ag-food according to result of skin titration

2. Patients with foods positive in three groups of tests (+ + +)

Adjustment of therapy according to tolerance and clinical results

This type of management presented in Tables IV and V is applied at present the 250 patients presented in the text were not managed in this way

sion as the ultimate etiological treatment one should not be substituted for the other If immuno-metabolic therapy combined with pharmacological decompression does not bring about complete or partial relief of clinical manifestations after twelve months of treatment, surgical decompression is in order *It must be strongly emphasized again that maintenance of immuno-metabolic therapy during and after successful surgical or pharmacological decompression is the only guarantee against a relapse of the disease* Discontinuation of the "etiologic" therapy of endolymphatic hydrops, if ever possible must be carried out stepwise and accompanied by laboratory studies of the abnormal features to be sure that these remain corrected. Decompressed patients when free or partially free of symptoms, are often unwilling to maintain the necessary metabolic therapy for many months, or for life. It must therefore, be impressed on these patients that they still harbour the insidious disease of dysproteinemia which may not only precipitate a recurrence of aural symptoms, but may also cause other syndromes derived from the same metabolic disease.

Pharmacologic decompression of endolymphatic hypertension

Lowering of the hyperosmolality of the endolymph can be accomplished by (1) administration of histamine or its analogues, (2) infusion of plasma proteins and/or plasma expanders to increase the relative osmolality of blood plasma.

Histamine hydrochloride or betahistine hydrochloride (Serc) *as decompressing agents of endolymphatic hypertension*

Histamine hydrochloride may be regarded as a hormone acting upon the microcirculation specifically on the precapillary constrictors (Schayer 1964) Histamine exists in all tissues in various quantities either in "free" form or "bound" to granules of the mast cells most likely connected with heparin (Schayer 1965). The "free" form of histamines may derive either from the "bound" form or may be de novo synthesized from histidine by decarboxylation this form of histamine Schayer (1965) called the induced histamine The "bound" form possesses no pharmacological action but many factors could release histamine (histamine liberators) thus making it "free" The degree of histamine effect is directly related to the quantity of "free" histamine. The phar

Table VI *Menière's disease and histamine cephalgia treated with pharmacological decompression*

	No. of Cases	Complete remission		Partial remission		No improvement		Deterioration	
		Abs.	%	Abs.	%	Abs.	%	Abs.	%

Histamine cephalgia	20	10	50.0	5	25.0	5	25.0	0	0

macological action of histamine has numerous effects, one of which is the relaxation of the precapillary constrictor leading to the substantial drop in blood pressure in the whole arterial system which may end, in advanced cases, in a vascular shock (Feldberg, 1953). The drop in the arterial head pressure in the precapillary system (in our case, in the *stria vascularis*) *may reduce the driving force* (see Fig. 1) of the filtration of water and water solutes from the capillaries into the extracapillary space (in our case, into the endolymphatic space). To accomplish this effect the dosage of histamine must reach the amounts which exhibits undesirable side-effects, e.g. wheal formation, exudation into various organs with manifestations from thus affected organs, etc. However histamine may bring about a transitory improvement in *Menière's disease* when applied sublingually or subcutaneously in an infinitesimally small amount, e.g., one to three drops of aqueous solutions ranging from 1 mg per million to 1 mg per 20 million. The effect of this therapy although harmless as far as side-effects of histamine is concerned, is unpredictable, and effective only in few cases of Menière's disease. Histamine administered orally is completely ineffective because it is destroyed by digestive enzymes.

Pharmaceutical industry has concentrated its efforts on formulating a histamine derivative which would retain its relaxing effect on the precapillary constrictor but be devoid of other undesired side-effects of histamine. *Betahistine hydrochloride* under the name of "Serc®" (Unimed, Inc., Morristown, New Jersey) has been studied from many pharmacological angles, and has been found to have an LD-50 about fifty times higher than that of histamine phosphate. Other side-effects are also reduced to an insignificant level, while its effect on relaxing of the precapillaries is fully retained but without the rapidity of the action exerted by histamine (Walter et al., 1941). We have, therefore, applied "Serc" orally in dosage 4 to 8 mg four times daily for decompression of endolymphatic hypertension (Godlowski, 1952). In this dosage, administered orally "Serc" is well tolerated in the majority of the cases of Menière's disease (Table VI). Only a few patients complained of general weakness caused by arterial hypotension this was easily remedied by oral administration of sympathomimetic drugs such as isoproterenol (Isuprel®) 15 mg three times daily. Hot flushes in the head occurred very rarely and responded to temporary discontinuation of "Serc" therapy with subsequent resumption at a lower dosage and gradually increasing to the recommended dose. On very rare occasions (less than 1%) higher doses of "Serc" could reactivate peptic ulcer hence in patients with active peptic ulcer or with history of it, this area should be carefully screened during the therapy with "Serc."

"Serc" has also been successfully used in other vascular pathologies such as histamine cephalgia (Horton & Van Leden, 1962), cerebrovascular senility syndrome (Horton & Van Leden, 1962), and angina pectoris (Horton & Van Leden, 1962).

cologic decompression, no improvement occurs within four weeks, surgical decompression should be advised.

A transitory response to the intravenous infusion of plasma or plasma expanders may provide some information as to the probable success of surgical decompression in the improvement of hearing. A transitory effect in any clinical manifestations produced by increased osmolality of the blood indicates that the structures of the inner ear remain in a reversible state and thereby further surgical intervention is justified. In other words, a mild and transitory improvement may be regarded as a good prognostic sign as to the probable effectiveness of surgical decompression as far as hearing is concerned. However our experience in this respect is too limited to rule out surgical decompression in cases in which such transitory improvement did not occur

Supportive medical therapy in endolymphatic hypertension

Supportive therapy of endolymphatic hypertension consists of various measures which would improve the condition of the whole organism (Derlacki, 1965).

1 Complete *omission of tobacco* is a basic necessity in controlling endolymphatic hypertension in mild as well as in heavy smokers. The toxic effect of tobacco on the equilibral labyrinthine system has been conclusively established (Derlacki, 1954 and others) in clinical and in experimental conditions.

2 *Low-sodium diet* containing no more than 250 mg of sodium per day (Godlowski, 1965) has been recommended for reducing tissue hydration (in this instance the labyrinthine hypertension) The following sources of sodium should be kept in mind. table salt, and other dietary items which may have high content of the sodium cation, baking powder bicarbonate of soda, Accent," various condiments, carbonated drinks, drinking water from softeners, etc.

3. In acute disabling forms of endolymphatic hypertension *intravenous infusion of histamine phosphate* 1 to 2 mg in 500 ml of 5% dextrose solution in five hours (Derlacki, 1954).

4. In acute attacks of endolymphatic hypertension various compounds may have a bene-

The initial dosage of "Serc" may be gradually reduced to the maintenance level which must be individually determined by trial and error. The beneficial effects of betahistine hydrochloride therapy in Menière's disease must be regarded as a palliative procedure and should be used only as a supplement to the etiological therapy.

Increased osmolality of blood plasma used for decompression of endolymphatic hypertension

The return of water and crystalloids from the endolymph into the blood at the venous end of the stria vascularis is attracted by the osmotic pressure of plasma proteins and electrolytes (see Fig. 2). Therefore, increasing the osmolality of the plasma by means of infusion of the concentrated plasma proteins (or plasma expanders) should increase the rate of return of water from the endolymph to the blood thereby assisting the decompression of the endolymphatic hypertension. An intravenous infusion of concentrated blood plasma or concentrated human blood albumin (25%) is the most physiological material for increasing the osmolality of plasma. The concentrated proteins infused intravenously remain in the blood for about three to four weeks, and then the infusion should be repeated. The plasma protein preparations available on the market contain 25 g of albumin in 100 ml. To effectively influence the osmolality of the blood and decompress endolymphatic hypertension is around 1 000 to 2 000 ml of concentrated plasma (15 g proteins per 100 ml) or 250 to 500 g of proteins should be infused at one time. The dosage is calculated in the initial content of plasma proteins and their qualitative distribution. For example if the initial protein content of the patient's plasma was around 7 gm per 100 ml, the desired target is 10 gm percent of protein in the patient's plasma at the end of infusion. The hyperosmolality produced by about 10 gm per 100 of proteins in the blood plasma should effectively decompress the endolymphatic hypertension. There are two dangers in this method. (1) possibility of transmission of infection (hepatitis virus) from the pooled plasma. (2) a too rapid increase in blood volume caused by its hyperosmolality with the fluid withdrawn from the tissues into the blood.

Prospective patients must therefore possess (*a*) a normal electrolyte and water balance (*b*) satisfactory excretory capacity of kidneys, (*c*) an evaluated electrophoretic plasma protein distribution (*d*) a known osmolality of blood plasma and (*e*) a cardiovascular system in a fully compensated state.

Our practice is to mix 100 ml of the plasma expanders such as "Osmitrol®" "Albumisol®" or "Dextran®" with every 500 ml of plasma. Patients selected for pharmacological decompression should remain on the immuno-metabolic management for three to six months prior to the attempt and for at least three to six weeks on full dose of "Serc" therapy. An evaluation of protein distribution in plasma, the electrolyte profile, the osmotic pressure of blood plasma, the pH of blood and the viscosity of the plasma, should be done about twenty-four hours prior to an infusion and repeated immediately afterward, in order to be reasonably certain as to whether or not the required physicochemical conditions necessary for decompression have been fulfilled. A determination of total plasma proteins of ±10 g percent indicate that the infusion should be terminated. Some patients may experience transitory mild vertigo immediately after the infusion, so they should be informed about this beforehand.

Improvement in clinical manifestations may be expected within a few hours which, in unsuccessful decompression will shortly disappear. On the other hand, the improvement may not start to take place until two or three days after the infusion, but then be maintained for as long as the hyperosmolality of the plasma persists. During the whole post infusion period the patient must remain on full scale immuno-metabolic management. If after properly executed attempts of pharma

logical mechanism persisted in the organism even during the remission obtained by the decompression. In his cases the pre- and post operative metabolic studies were not reported.

R. J. Wolfson et al. (1968) applied cryosurgery to the horizontal semicircular canal chiefly for the relieving of vertigo of labyrinthine origin but disturbing the hearing only in very few patients.

F. D. Austin (1965) has modified the artificial fistulation between the sac and subarachnoid space by introducing a strip of thin foil in an attempt to prevent healing of the fistula. Reported early results were slightly better than those reported by others, but he also recently introduced modification in the fistulation technique (personal communication).

J. L. Pulec (1968) applied an otic-perotic shunt connecting scala media with scala tympani by a platinum tube; the author himself recommends this method only for those patients with endolymphatic hypertension in which other shunt operations have failed to relieve the vertigo.

J. Shea (1966) introduced a teflon prosthesis for the maintenance of fistula in the sac hoping to avoid the errors encountered by other techniques.

G. E. Shambaugh, Jr. (1966, 1968) applied a different technique for relieving the manifestations of endolymphatic hydrops. By enlargement of the bony encasement and relieving the pressure of that part of dura mater which covers the sac he provided more space for a spontaneous expansion of the whole endolymphatic space. Moreover by implanting a pedunculated muscle flap he hoped to bring better capillary circulation to the perisacal space and thereby to increase the secretory function of the sac. This conservative technique eliminates shunting the endolymph into perilymph or CSF and therefore retains the physiological hydrostatic conditions of the inner ear. However, in my opinion, after an initial improvement, persisting dysproteinemia with persisting hyperosmolality of the endolymph will, sooner or later, precipitate a relapse of the symptoms of endolymphatic hypertension. If, however, prior to the surgery and during the period of relief after surgery an intensive therapy of the dysproteinemia be instituted, the chances of permanent remission should be increased.

None of the authors claim a cure of what they term Menière's disease by surgical de-

ficial but inconsistent effect. "Antivert®" tablets (Roerig Company) 3 to 8 tablets per day are often helpful in controlling the annoying vertigo Bonine® (Pfizer Company) is recommended in 25 to 100 mg daily for protracted nausea and vomiting "Dramamine® (Searle Company) in tablets, suppositories and injections, in dosage of 50 to 500 mg may also occasionally interrupt the attack of vertigo. All these compounds possess antihistaminic effect so probably their alleviating action operates in vertigo connected with allergic reactions. Dilantine® (Parke Davis) 100 mg 1 to 3 capsules a day could be applied in protracted vertigos.

5 *Nicotinic acid* is a powerful vasodilating agent acting upon the arterioles and metarterioles and precapillary sphincter muscle of venules by this action the capillary circulation slows down and hydrostatic pressure drops down thereby reducing the rate of filtration in the stria vascularis and slowing production of endolymph. It also accelerates the reabsorption of water by the collecting venules thus reducing the volume of endolymph and improving the nutrition of the organs within the endolymphatic space. The effective dosage of nicotinic acid fluctuates between 500 to 8 000 mg per day Nicotinic acid, apart from a potent vasodilating effect possesses also important action in the metabolic process of protein formation.

Surgical decompression of endolymphatic hypertension

Surgical decompression of endolymphatic hypertension (if associated with hydrops) is attained by the formation of a fistula either (*a*) between the saccule and the vestibule or (*b*) between the endolymphatic sac and the surrounding structures containing free flowing fluids (subarachnoid space), or (*c*) by enlargement of the bony encasement in which the sac is located. The reader may find the details of each procedure in the quoted references.

G Portmann in 1926 and 1927 was the first to advocate fistulation of the endolymphatic sac to relieve endolymphatic hypertension but no attempt was made to secure permanent patency of the fistula. The results were remarkable for a short period of time, but two-thirds of the patients sooner or later relapsed. However by using a modification of the technique the results were highly successful in some patients over a long period (Portmann 1964)

W F House (1964) improved Portmann's technique by applying a shunt between the sac and subarachnoid space using a plastic prosthesis to keep the fistula open He (1968) has recently modified his initial operation by eliminating the prosthesis completely and has maintained an open fistula by applying cryo-otic-perotic shunt to the promontory thereby connecting the endolymphatic with perilymphatic spaces, thus equalizing the pressure in both compartments. His results chiefly in the relief of vertigo were somewhat better than those of Portmann. However when these technical devices failed, the episodes of vertigo promptly returned proving that the etio-

ficial but inconsistent effect. "Antivert®" tablets (Roerig Company) 3 to 8 tablets per day are often helpful in controlling the annoying vertigo "Bonine®" (Pfizer Company) is recommended in 25 to 100 mg daily for protracted nausea and vomiting "Dramamine®" (Searle Company) in tablets, suppositories and injections, in dosage of 50 to 500 mg may also occasionally interrupt the attack of vertigo All these compounds possess antihistaminic effect so probably their alleviating action operates in vertigo connected with allergic reactions. "Dilantine®" (Parke Davis) 100 mg 1 to 3 capsules a day could be applied in protracted vertigos.

5 *Nicotinic acid* is a powerful vasodilating agent acting upon the arterioles and metarterioles and precapillary sphincter muscle of venules by this action the capillary circulation slows down and hydrostatic pressure drops down thereby reducing the rate of filtration in the stria vascularis and slowing production of endolymph. It also accelerates the reabsorption of water by the collecting venules thus reducing the volume of endolymph and improving the nutrition of the organs within the endolymphatic space The effective dosage of nicotinic acid fluctuates between 500 to 8 000 mg per day Nicotinic acid apart from a potent vasodilating effect possesses also important action in the metabolic process of protein formation.

Surgical decompression of endolymphatic hypertension

Surgical decompression of endolymphatic hypertension (if associated with hydrops) is attained by the formation of a fistula either

(*a*) between the saccule and the vestibule, or (*b*) between the endolymphatic sac and the surrounding structures containing free-flowing fluids (subarachnoid space) or (*c*) by enlargement of the bony encasement in which the sac is located. The reader may find the details of each procedure in the quoted references.

G Portmann in 1926 and 1927 was the first to advocate fistulation of the endolymphatic sac to relieve endolymphatic hypertension, but no attempt was made to secure permanent patency of the fistula. The results were remarkable for a short period of time but two-thirds of the patients sooner or later relapsed. However by using a modification of the technique the results were highly successful in some patients over a long period (Portmann 1964).

W F House (1964) improved Portmann's technique by applying a shunt between the sac and subarachnoid space using a plastic prosthesis to keep the fistula open He (1968) has recently modified his initial operation by eliminating the prosthesis completely and has maintained an open fistula by applying cryo-otic perotic shunt to the promontory thereby connecting the endolymphatic with perilymphatic spaces, thus equalizing the pressure in both compartments. His results, chiefly in the relief of vertigo were somewhat better than those of Portmann However when these technical devices failed the episodes of vertigo promptly returned, proving that the etio-

logical mechanism persisted in the organism even during the remission obtained by the decompression. In his cases the pre- and postoperative metabolic studies were not reported.

R. J. Wolfson et al. (1968) applied cryosurgery to the horizontal semicircular canal chiefly for the relieving of vertigo of labyrinthine origin but disturbing the hearing only in very few patients.

F. D. Austin (1965) has modified the artificial fistulation between the sac and subarachnoid space by introducing a strip of thin foil in an attempt to prevent healing of the fistula. Reported early results were slightly better than those reported by others, but he also recently introduced modification in the fistulation technique (personal communication).

J. L. Pulec (1968) applied an otic-perotic shunt connecting scala media with scala tympani by a platinum tube; the author himself recommends this method only for those patients with endolymphatic hypertension in which other shunt operations have failed to relieve the vertigo.

J. Shea (1966) introduced a teflon prosthesis for the maintenance of fistula in the sac hoping to avoid the errors encountered by other techniques.

G. E. Shambaugh, Jr. (1966, 1968) applied a different technique for relieving the manifestations of endolymphatic hydrops. By enlargement of the bony encasement and relieving the pressure of that part of dura mater which covers the sac he provided more space for a spontaneous expansion of the whole endolymphatic space. Moreover by implanting a pedunculated muscle flap he hoped to bring better capillary circulation to the perisaccal space and thereby to increase the secretory function of the sac. This conservative technique eliminates shunting the endolymph into perilymph or CSF and therefore retains the physiological hydrostatic conditions of the inner ear. However, in my opinion, after an initial improvement, persisting dysproteinemia with persisting hyperosmolality of the endolymph will, sooner or later, precipitate a relapse of the symptoms of endolymphatic hypertension. If, however, prior to the surgery and during the period of relief after surgery an intensive therapy of the dysproteinemia be instituted, the chances of permanent remission should be increased.

None of the authors claim a cure of what they term Menière's disease by surgical de-

compression of the endolymphatic space although long-term observations have shown what appears to be a complete remission in some cases reported spontaneous remissions of five years duration must always be kept in mind in cases of therapeutic remissions. In these cases relief of the endolymphatic hypertension may have permitted the organism itself to correct the reversible aural pathology in some unknown manner especially if the existing metabolic error had a self limiting character However to hope for such an exceptional result and to routinely advise surgical decompression as the sole therapy in endolymphatic hypertension reflects an oversight in consideration of the concept of the biological process involved

Destructive surgery in the management of endolymphatic hypertension

Destruction of the inner ear should have a restricted application in the treatment of endolymphatic hypertension Destruction of the end organs in the inner ear may be accomplished either by a surgical procedure or by high frequency ultrasonic beam (Arslan, 1953 Ariano 1966) Both methods must be regarded as unphysiological, and as such, should be applied only to those patients who are incapacitated by vertigo and have a profound and probably irreversible hearing loss in the affected ear refractory to a prolonged and intensive immuno-metabolic therapy supplemented by medical and surgical decompressions.

Conclusions

1 Endolymphatic hypertension (Menière's Disease—Labyrinthine Hydrops) is a local expression of a generalized molecular disease of proteins which exists in the whole organism.

2 A deficiency in the depolymerizing action of hyaluronidase may lead to the accumulation of hydrophylic hyaluronate mucopolysaccharides in various parts of the organism, the specific location of the endolymphatic space in a narrow bone encasement may precipitate the clinical symptoms as a result of relatively mild hyperosmolality of the endolymph, whereas other organs involved in a similar disease and subjected to the same gradient of osmotic increase in the tissue fluids, do not respond with such dramatic manifestations as that of endolymphatic space.

3. The immuno-metabolic management of endolymphatic hypertension consists of the application of six therapeutic agents outlined in "The general principles of immuno-metabolic management" (Godlowski, 1965).

4. Conservative and/or surgical decompression of endolymphatic hypertension may facilitate the recovery of the aural disease, but immuno-metabolic management must be applied concurrently sometimes for life.

5 Decompression of endolymphatic hypertension may be attempted by either pharmacologic or surgical methods.

6. Both methods of endolymphatic decompression are mainly palliative procedures which fail to take into consideration the probable physiologic dysfunction that results in both pathological changes and the symptoms.

Acknowledgment

I wish to acknowledge the reading and editing of the manuscript by Dr Henry Williams, Professor Emeritus of the Ear Nose and Throat Department, Mayo Clinic, Rochester Minnesota, and for making many suggestions; also my thanks to Marseille Spetz, M.D., Medical Editorial Consultant, for reading the proofs.

I also wish to thank Dr David Austin, Professor of Ear Nose and Throat Department, University of Illinois, Chicago Illinois, for supplying the material which otherwise would not have been available to me.

My appreciation is also extended to Dr V Pullets, attending physician in the Ear Nose and Throat Department, Mayo Clinic, Rochester Minnesota, for sending the material used in my studies which would not have been available to an internist.

CONTENTS

I Introduction

Similar to other sensory receptors, the inner ear operates as a transducer in which the input signal serves as a trigger to initiate a transduction process energized by a metabolic source.

The discovery of the dc resting endolymphatic potential by Bekesy (1952) suggested the need to explore the metabolic pathways that controlled this phenomenon, since at that time it was already known that the other cochlear potentials were at least partially maintained by oxidative processes (Wever et al. 1941 Wever et al., 1949). Also the finding of high potassium levels in the endolymph (Smith et al., 1952: Smith et al. 1954), requiring powerful energy driven transport processes for its maintenance, re-emphasized the need for studies on the bioenergetics of the inner ear system.

The general concept was that the organ of Corti, due to its lack of capillaries and its remoteness from blood supply should have ample facilities for energy storage and anaerobic energy production the stria vascularis being a highly vascular structure, could probably depend more on oxidative metabolism and short term energy supply However because of the microscopic size, anatomic peculiarities of the tissues involved, and the difficulties encountered in obtaining and preparing the temporal bone, the studies pertinent to the energy metabolism of the cochlea have begun only recently

After the original histochemical demonstration, that the main energy supply to the brain is provided by oxidative glucose catabolism (Lowry 1953) Wing showed that in insulin-induced hypoglycemia, the cochlear microphonic was diminished quite markedly (Wing, 1959). Koide (1958), had shown that the reduced cochlear microphonics in insulin-induced hypoglycemia returned back to its normal values after injection of glucose or other citric acid cycle substrates. Two years later he demonstrated the adverse effect of various citric acid cycle inhibitors on the cochlear microphonics (Koide et al., 1960). Vosteen (1960) showed that the stria vascularis had high levels of enzymes for aerobic metabolism (such as succinic dehydrogenase, and those of the cytrochrome oxidase system), but had low levels of anaerobic metabolic enzymes such as lactic dehydrogenase. On the other hand, the organ of Corti had high levels of those same oxidative (aerobic) enzymes (not as high as the stria vascularis), but had high levels of lactic dehydrogenase (anaerobic) enzymes as well.

This chain of experiments, then shows that the inner ear is dependent on glucose metabolism, and that it is primarily aerobic.

With the refinement of bioelectric techniques, a more precise localization of cochlear events was possible. Thus, it was established that the cochlear microphonic has its origin in or near the hair cells, and the dc resting endolymphatic potential requires an intact stria vascularis for its existence (Bekesy 1951 Davis, 1956 Davis, 1958 Tasaki & Spyropoules, 1959: Davis, 1965 Wever 1966). With these techniques, it is possible now to examine in a dynamic way some of the metabolic processes involved in the inner ear function.

Diabetes mellitus is a chronic disorder of carbohydrate metabolism which is believed to result from relative or absolute insulin deficiency In addition to the severe metabolic disturbances, widespread pathological changes in the human body have been observed. These changes are basically vascular and consist of two types (Seftel & Walker 1966): nonspecific

large vessel disease and a specific small vessel disease or microangiopathy These changes are generalized throughout the body and indeed the few histological studies of temporal bones of human diabetics (Jørgensen 1961 Jørgensen 1963) and experimental animals (Costa 1967) show changes in the small blood vessels of the stria vascularis and the modiolus. These changes are apparently not specific but are more pronounced than those seen in "presbycusis" Sixteen to forty per cent of adult onset diabetes are found to audiometrically proven bilateral, symmetrical high frequency sensory neural hearing loss (Abu Khatwa et al., 1961 Zelenka & Kozak 1965 Ancona, 1956 Borsuk et al. 1956 Strubinski & Malicka 1966 Tota & Bocci, 1965 Vigi, 1950 Profatio & Baralelli, 1959 Marullo 1950 Jørgensen 1969 Jørgensen & Buch 1961) On the other hand juvenile onset diabetics are found to have normal pure tone audiograms, but show changes in the Bekesy tracings, the nature of which remain speculative (Marshak & Anderson 1968) The hearing loss associated with diabetes mellitus then may be a result of localized microangiopathy in the inner ear but it might also be due to derangement in the metabolism of glucose or a combination of the two

Recently the antibiotic streptozotocin derived from streptomyces Achromogenes was found to be diabetogenic (Vavra et al. 1959–1960 Herr et al. 1959–1960) Several studies have shown its specific destructive effect on the beta cells of the pancreas of experimental animals (Rableten et al. 1963 Brosky & Logathetopoulos, 1969) and of patients with functional islet cell carcinoma (Sado 1969) However the fact that no vascular changes have been observed using this drug (Arison et al., 1967) makes it an ideal tool to study the effect of pure and severe metabolic disturbance on the bioenergetics of the hearing processes.

PURPOSE

The purpose of this study was to examine the function of the inner ear of chinchillas suffering from chronic disturbance of glucose metabolism.

We elected to use chinchillas because of the stability of their hearing level over a long period of time. Long term experiments with the guinea pig are doomed because so many of them develop bony ankylosis and fixation of the ossicles. The intracochlear potential recording from the cat and other commonly used animals in auditory physiology is still fraught with great technical difficulties, in addition to the fact that their hearing level deteriorates with time

These chinchillas were rendered "diabetic" by partial selective medical pancreatectomy caused by the injection of streptozotocin. Cochlear function was assessed by studying the cochlear microphonic (CM) as an index of hair cell function and the dc resting endolymphatic potential (EP) as an index of the metabolic activity of the stria vascularis.

II Methods

1 Experimental animals. the study was performed on nine young healthy chinchillas, weighing 400–500 g ("Control" group) and 10 "diabetic" chinchillas of the same age and weight. Both groups were fed Alfalfa chinchilla diet and water ad libitum No insulin was administered.

2. Induction of the "diabetic" state was carried out by a single intraperitoneal injection of 100–120 mg/kg body weight of streptozotocin (NSC 37917) This state was maintained for 12–18 months prior to testing.

3 Drug formulation the drug was prepared aseptically as 1% solution in saline buffered

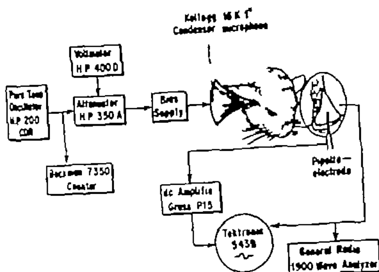

Fig. 1 Equipment used for delivering the signal and response recording.

with anticoagulant acid citrate dextrose solution (1 50 dilution A.C.D U.S.P with 0.9% sodium chloride). The pH of the solution was 5.0. The solutions were made fresh daily since the compound is very unstable. Freshly prepared solutions are crystal clear and have a light straw color On standing they take on a yellow to dark brown color and effervesce—both changes are indicative of instability of the compound.

4. Monitoring of the diabetes was carried out by checking for glycosuria twice a week with clinistix

5 Blood sugar was determined by the alkaline potassium ferricyanide method with Technicon Autoanalizer modification (Hoffman, 1937)

6 Surgical procedure. with the chinchilla anesthetized and supine the head was held in a custom-designed head holder A 3 cm incision through skin and platysma parallel to the body of the mandible was carried out. By sharp and blunt dissection the bulla was exposed after the overlying muscle was divided between ligatures. The bulla was entered using a mm cutting dental burr or exavators and the opening was enlarged with rongeurs. The mucosa over the elongated cylindrically-shaped cochlea was stripped with a straight ear pick so as to bare the basal and the second turn. Using a 1 mm polishing burr the lateral aspect of the otic capsule of the basal turn was flattened slowly until the blue line" was seen. A perforation through the bone was done by manual twisting of a root canal reamer 0.1 mm tip diameter The wire electrode fitted snugly into the hole was cemented to the margins of the cochlea with Caulk grip cement.

For the endolymphatic dc potential recording, either the same hole was utilized or another hole was drilled directly over the spiral ligament of the same ear or the contralateral one.

7 Electrodes:

(*a*) For the CM recording, 100 micron Teflon coated nonpolarizable nichrome wire was used.

(*b*) For the dc recording, micropipettes were pulled by Automatic Vertical Pipette Puller (David Kopf Instruments, model 700B) from pyrex glass tubing of approximately 1 mm in its external diameter The external tip diameter of the micropipette was 3–5 micron with tip resistance of 5–15 megohms.

By placing these micropipettes tip down, in

a 3 molar KCL bath thus solution passively diffused to partially fill the pipette An occasional air bubble was displaced with minute wire.

(*c*) The micropipette was connected to the amplifier with a chloridized silver wire

Chloridization was carried out at the anode in a bath containing 0 1 M Hydrochloric acid. A potential difference of 2 or 3 volts between bath and electrode was maintained for 30 minutes.

8 Instrumentation and Measurements the signal system consisted of pure tone oscillator (Hewlett Packard 200 CDR) attenuator (Hewlett Packard 350A) and a 200 volt bias supply (custom made) which was connected to a Kellog model 16K 1 condensor microphone. Short pips of pure tone from 500 Hz to 4 000 Hz that were produced by the oscillator the frequency of which was monitored by a Beckman 7350 counter were coupled to the partially excised external auditory canal of the chinchilla through a modified ear speculum.

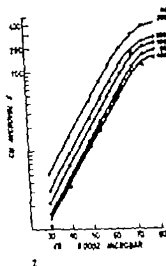
The potential differences between the intracochlear electrode and an indifferent electrode in the neck muscles were measured with a General Radio 1900 wave analyzer and at the same time were seen on a Tektronix 543B oscilloscope.

The dc potential recorded from the scala media was amplified 100 × by dc amplifier (Grass P 15) and measured on the oscilloscope (Fig 1) In this manner the correct position of the exploring micropipette could be ascertained.

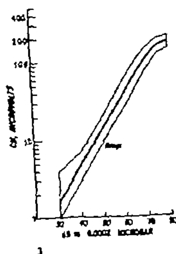
At the end of the procedure the animals were sacrificed and biopsies from the liver kidney spleen and pancreas were obtained. Microscopic sections were cut at 12 microns and stained with hematoxylin and eosine.

III Experimental Design and Procedure

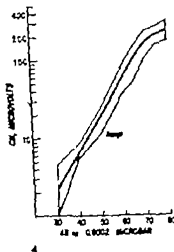
Normal and diabetic" chinchillas were studied on alternate days, and were kept fasting over night Because of the difficulty in obtaining blood samples, only one sample from each animal was submitted for sugar determination. This was obtained by excising the tip of the tail immediately after the animal was anesthetized.



Recording of the CM was then carried out in a duobly walled sound treated room (Industrial Acoustics Company Inc)



Measurements of the CM for each animal for each frequency were obtained twice first when the signal intensity was gradually increased to reach the peak response the second measurement was taken while gradually decreasing the signal intensity



The recording of the CM was carried out from one ear and the dc potential from the other ear either by penetrating the spiral ligament or through Reissner s membrane.

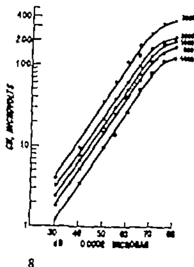
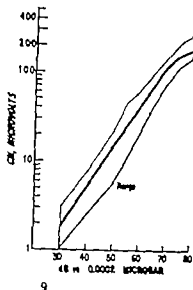
whereas the response of this group to 500 Hz, 1 000 Hz, 2 000 Hz, 3 000 Hz, and 4 000 Hz is shown in Fig. 9 10, 11 12 and 13 respectively

The magnitude of the dc endolymphatic potential was measured in four chinchillas in each group as seen in Table II. In three chinchillas in each group, the electrode was introduced to the scala media through the spiral ligament, in one chinchilla in each group the micropipette was pushed through Reissner's membrane. By manipulating the micromanipulator back and forth, after entering the scala media, three measurements were obtained for each animal.



While monitoring the passage of the micropipette through the spiral ligament and stria vascularis, the dc potential was never more than a few millivolts, and occasionally was even negative, for a brief period of time, relative to the inactive electrode placed in the neck muscle.

However when the electrode was pushed further inward, there suddenly appeared a large positive potential, of 70–85 millivolts in magnitude, which remained unchanged as long as the electrode stayed in that position. At this point, there was always an increase in the microphonic response picked up by the same electrode up to 2–5 millivolts.



The statistical analysis of the responses of the two groups at each frequency tested is shown in Tables 3, 4 5 6, and 7 The similarity between the functions of the two groups is striking, both in terms of the maxima of the responses and in terms of the slope of the curves. Indeed, the difference between the two groups is insignificant except for their

responses at 3 000 Hz tone at 30 dB and 40 dB which may reflect a recording error or could have happened by chance alone.

The only study of cochlear microphonics in normal chinchillas was reported by Strother in 1967 (Strother 1967) His active electrode was placed on the round window membrane. Since there are no differences between the diabetic" and the control group in our study the 19 chinchillas can be treated as one group indeed, except for a slight decrease in the maxima of the response in all frequencies tested, Strother s curves and ours compare favorably in terms of the slope and the linear and non linear portions of the function

The values for the dc endolymphatic potential in our group—70–85 millivolts—is of the same magnitude as was reported for cats, guinea pigs monkeys (Fernandez et al. 1962) as well as for chinchillas (Eldredge 1968)

Several factors could account for the fact that the cochlear potentials were not affected in our "diabetic" group

1 The role of insulin in glucose metabolism is still debatable. However the majority of investigators share the opinion that it facilitates the penetration of glucose into the cell to be utilized for energy production or to be stored as glycogen (*Cecil Loeb Textbook of Medicine* 1963) This phenomenon has been demonstrated in many tissues, except in the brain and in the liver where glucose utilization is not insulin dependent Since the cochlea is a neuroepithelial structure, it is possible that its glucose metabolism is insulin independent. In this case, in spite of the fact that insulin production was partially or totally curtailed (as in our diabetic" group) the glucose-dependent hearing processes will not be affected.

2. After this study was started, a method of chemical microanalysis of individual cell types of the cochlea was developed (Matschinsky et al. 1968). The importance of this method is in the fact that the analysis is carried out without alteration of metabolic pattern: this is achieved by rapid freezing of the cochlea and analyzing microsamples of individual cell types. Using this method, Matschinsky & Thalman found (1967, 1970) that the glycogen levels in the organ of Corti of the guinea pig are very high—approximately ten fold higher than demonstrated in the average brain but the same order of magnitude found in the average rabbit retina. The amount of glycogen in the stria vascularis was considerably less. Of interest is the fact that the main localization of this glycogen stores is in the external hair cells. However, in addition to this large amount of stored energy, a high level of glucose was found in the organ of Corti. It was found to be located largely in the extracellular space but is readily available for immediate use, or when the stored glycogen is depleted—a situation which might theoretically exist in the hypoinsulinemic chinchilla.

3. The general angiopathy might involve the central auditory pathways (Reske-Nielsen et al. 1965, Dolman, 1963, Fagerberg, 1959) and cause a hearing loss which will not be manifested by changes in the cochlear potentials.

V. Summary and Conclusions

Sustained hyperglycemia without generalized microangiopathy was induced in 9 chinchillas and maintained for 12–18 months by a single intraperitoneal injection of streptozotocin 100–120 mg/kg body weight.

Inner ear function in these chinchillas measured by unipolar intracochlear recording of the cochlear microphonics and the dc resting endolymphatic potential was found to be normal.

The hearing loss found in human diabetics might possibly be due to the generalized angiopathy affecting the capillaries of the basilar membrane. These capillaries are supplied by different routes than those supplying the stria vascularis (Axelsson, 1968). The role of these capillaries as providing the organ of Corti with oxygen and nutrients may be far more important than generally realized (Lawrence, 1966). Indeed, the hearing loss caused by noise stimulation (Lawrence et al. 1967) and ototoxic drugs (Hawkins, 1967, Lawrence, 1970) may be primarily due to damage to these capillaries. Thus, the absence of angio-

pathy in the injected group of chinchillas could certainly explain the normal cochlear potentials by the same token the etiology of the hearing loss found in human diabetics might possibly be explained on the basis of the diabetic microangiopathy affecting the capillaries of the basilar membrane (vas spirale)

VI Acknowledgment

I would like to extend my gratitude to my thesis supervisor Dr A. M Small, Jr His patience, support and encouragement were indispensable during the entire project.

I wish to express my appreciation to the following men who have contributed their time and facilities in helping me with this project Dr J Wernick Dr Donald H Eldredge Dr Jane Collins, Dr J Carney Mr J Thews, and William E. Dulin, Ph.D (The Upjohn Company) for supplying the streptozotocin Without their help and cooperation this project would not have been possible

This study was supported in part by PHS training grant 5TO1 NS05116-14

pathy in the injected group of chinchillas could certainly explain the normal cochlear potentials by the same token the etiology of the hearing loss found in human diabetics might possibly be explained on the basis of the diabetic microangiopathy affecting the capillaries of the basilar membrane (vas spirale)

VI Acknowledgment

I would like to extend my gratitude to my thesis supervisor Dr A. M. Small Jr His patience, support and encouragement were indispensable during the entire project.

I wish to express my appreciation to the following men who have contributed their time and facilities in helping me with this project Dr J Wernick Dr Donald H. Eldredge Dr Jane Collins, Dr J Carney Mr J Thews, and William E. Dulin Ph.D (The Upjohn Company) for supplying the streptozotocin Without their help and cooperation this project would not have been possible.

This study was supported in part by PHS training grant *5TOI NS05116-14*
